THE PREVENTION AND RELIEF OF POST-OPERATIVE INTESTINAL OBSTRUCTION.[1]

BY CLEMENT CLEVELAND, M.D.,

NEW YORK.

By the term "post-operative" in this paper is meant that form of acute obstruction which follows abdominal section and is indirectly due to it. But there is some other cause beside the mere opening into the abdominal cavity to account for it. I refer here not to the adynamic type, due to intestinal paralysis from peritonitis, nor to that due to opium.

At the end of the first twenty-four hours following abdominal section, one of the first questions that occur to the surgeon is, whether gas has passed from the bowels. If this has occurred it is a presumption of favorable progress. In nine cases out of ten, if this has occurred, there is very little likelihood of peritonitis supervening. If there is obstruction to the passage of gas due to the oncoming of peritonitis, there are likely to be other signs, such as increased temperature, pulse, and respiration. Cases of this kind vary in severity, from those easily relievable to those that run on for days, exhausting the patient and threatening life. At the beginning the patient complains merely of the pain caused by her inability to void the gas, but should the obstruction be unrelieved, distention with nausea and vomiting is sure to follow, the location of the obstruction determining the intensity of the symptoms. If it be high up in the small intestines, nausea and vomiting are greatest, while, if it be low down, below the ileo-cæcal valve, distention will be most marked. This form of obstruction is not usually difficult to differentiate from the adynamic form due to peritonitis. In the latter there are usually increased temperature, pulse, and respiration, with more and continuous pain from the beginning. With the former there may be slight rise of temperature and increase of pulse beat, but the respiration remains nearly normal. This point I have constantly observed and have learned to rely upon as a favorable diagnostic sign. I do not mean that it is an invariable sign, but that it is an encouraging and valuable one.

The etiology of this form of obstruction is, I think, clear. The peritoneum is a most sensitive and delicate membrane, and any handling, no matter how gentle, causes the excretion of plastic lymph. In any abdominal operations for the removal of tumors or other diseased structures, there must be more or less handling of intestines. There are likely to be distortions and flexions, which become more and more fixed as time goes on by the plastic lymph thrown out about them. This is attested by the conditions found on reopening the abdomen after operation. The intestines or omentum may be found adherent to the abdominal incision or to some serous surface. It is surprising how insignificant an adhesion will produce obstruction. I remember a case that occurred in the practice of a friend, in which the patient died from exhaustion due to obstruction. On post-mortem examination a small intestine was found very slightly attached to an ovarian stump, causing a flexion of the gut and complete obstruction.

I have observed in cases in which it was impossible, from one cause or another, to keep the intestines away from the field of operating and necessitating constant handling in order to proceed with the operation, that there was always the greatest difficulty in effecting the passage of gas and fecal material. This fact I have repeatedly observed, and have expected obstruction to follow when it was not possible to protect the intestine. Formerly such cases were many. To-day, thanks to modern methods and equipment, they are generally avoidable. The old saying, "An ounce of prevention is worth a pound of cure," was never more applicable than here.

There are a number of measures upon which the greatest reliance may be placed as factors in the prevention of undue intestinal handling: the instituting several days beforehand of the preparations for the operation, in the way of restricting diet, and preparing the bowels by thorough evacuations, that the intestinal tract may be free from gas and fecal contents at the moment of operation; the irrigation of the rectum just before the operation. These are initiatory steps of great importance.

There is one great invention that has had an incalculable influence in the progress of modern abdominal surgery, and has made the name of its author immortal. I refer to the Trendelenburg posture. By its employment the intestines are carried toward the diaphragm, out of the field of operation. I am, of course, speaking as a gynæcologist and take it for granted that I am understood to be referring to pelvic surgery.

Before proceeding to an examination of the pelvic contents, after opening the abdomen, it is wise to place the patient in the Trendelenburg posture and carefully to cover the intestines with the omentum, when it is extensive enough, and then thoroughly, with wet pads of gauze, and gently to force the intestines still farther into the upper abdominal cavity. Wet pads are preferable to prevent their adhering to the intestinal surfaces and dragging upon them on removal. The design of the Trendelenburg position was to facilitate the operation, but the protection it affords to serous surfaces is manifestly of equal importance.

It is necessary, as far as possible, to be particular to leave no raw surfaces; to cauterize or cover with peritoneum every stump or particle of raw tissue.

It is customary with most surgeons to-day, I think, to use decinormal salt solution with which to irrigate the abdominal cavity. Many leave the cavity half filled with it on closing the incision. It serves by its rapid absorption, as well if not better than an intravenous infusion of the same solution, to stimulate the patient and lessen shock. It may even lessen the amount of plastic lymph thrown out, and thus, and by its own presence, lessen the amount of adhesions.

Concerning the methods of relief in obstruction. In the treatment of this condition I have for a year or more been much interested in the insufflation of oxygen gas. Hydrogen, carbonic acid gas, air, and hydrostatic

[1] Read at a meeting of the Practitioners' Society, December 7, 1900.

pressure have been used in the treatment of intussusception and other intestinal obstructions, and possibly oxygen may have been used for the same purpose; but, if so, I have been unable to find any record of it. I am not seeking to claim originality, but rather to find an excuse for speaking of it before this society. I have had occasion during the past year to make use of it a number of times. Its efficacy has been so marked in my hands that I have been greatly impressed with its importance as an agent of relief in this form of obstruction. There seems to be a question whether liquids can be forced beyond the ileocæcal valve, but Senn has demonstrated that hydrogen can be forced from the anus to the mouth. To illustrate the use and effect of the gas, I will relate the essential points in the histories of several cases of abdominal section.

Case I.—Miss M——, aged thirty-five years. Operation, abdominal hysterectomy for uterine fibroids. The operation was difficult by reason of distended intestines. Great difficulty was experienced in keeping them away from the field of operation, necessitating much handling.

First day. Much nausea and vomiting, with constant pain in the abdomen from gas, were present. T., 101.6°; P., 136; R., 20.

Second day. There has been no escape of gas since the operation. Frequent nausea and vomiting occurred. The abdominal pain from gas increased. Distention existed, and the rectal tube was passed without result. Calomel gr. ss. was given several times at an interval of an hour, and was vomited each time. Evening, T., 101°; P., 128; R., 22.

Third day. There has been no escape of gas since the operation. The patient vomited many times during the day. In the latter part of day, calomel gr. v. was given and retained. Several hours later, an enema of soap suds, sweet oil, and turpentine was given and repeated after several hours, with no result except the return of the enema. Irrigation of the bowel through Kemp's tube had no result. Constant and violent peristalsis with very severe pain was present, and the abdominal distention increased. Oxygen was administered per rectum. The gas was introduced very slowly for five or six minutes until the patient complained of the pain and distention. On breaking connection with the oxygen cylinder great quantities of flatus were expelled through the rectal tube, with the distinct odor of sulphurated oxygen. The patient was instantly relieved of pain and distention, and the bowels were moved thoroughly two hours later without any other agent being employed. There was no further trouble with the case.

Case II.—Mrs. B——, aged forty years. Operation, abdominal hysterectomy for uterine fibroids.

First day. Much pain and gas were noted. Nausea and vomiting were frequent, and eructations occasionally occurred.

Second day. There has been no expulsion of gas since the operation. The abdominal pain from the gas was severe. Calomel gr. ss. was given at intervals of an hour until two grains had been taken. Nausea and vomiting were frequent. T., 100.8°; P., 82; R., 20.

Third day. There has been no expulsion of gas since the operation. Calomel gr. iii. was given, followed by a half-ounce of sulphate of magnesium, and a high enema four hours later, without result. The abdominal pain and distention increased. Evening, T., 101.2°; P., 90; R., 20.

Fourth day. The patient thought she had expelled a little flatus. Nausea was constantly present and the abdominal distention was much increased. There was much pain from gas, and the patient was extremely weak. An insufflation of oxygen gas was made and much flatus was expelled at once. The bowels moved freely about ten minutes later. Nausea and vomiting, pain and distention, all were markedly relieved at once, and no further difficulty was experienced with the case. The patient made a good recovery.

Case III.—Miss C——, aged thirty-eight years. Operation, laparotomy for abdominal cyst, which proved to be a cyst of the right kidney. The contents were evacuated and the cyst was stitched to the abdominal incision. In drawing the suture tight to tie, on the right side of the incision a coil of small intestine was drawn, a little more snugly than I liked, against the abdominal wall. I was concerned that it might interfere with the free movement of the intestinal contents. It could not be helped, however. There had been, moreover, a good deal of unavoidable handling of the intestines.

First day. At the end of the first day the patient suffered severely from gas.

Second day. There has been no passage of gas since the operation. The rectal tube was inserted without result, but the patient was somewhat relieved by belching. She continued to suffer from colic during the day. The rectal tube was passed a number of times without result. An enema likewise was given without result. The patient belched and vomited liquid. There were constant nausea and frequent vomiting. Calomel gr. ss. was given and repeated every half-hour until two grains had been taken. Four hours later Epsom salts ℥ ss. was given and immediately vomited. At the end of three hours another ℥ ss. dose of Epsom salts was given and retained. A soap-suds and sweet-oil enema was given. A little gas was expelled, but no other results were obtained.

Third day. The patient was weaker, her abdomen was distended, and she was belching gas constantly, which gave some relief. An enema of soap suds, sweet oil, and turpentine was given and expelled. The rectal tube was passed a number of times without result. She vomited greenish fluid a number of times. An insufflation of oxygen gas was made through the rectal tube carried into the sigmoid flexure. The gas was allowed to pass in very slowly until the patient complained of severe pain. A great deal of gas, flatus, and liquid stool was expelled as a result, and later there followed a large liquid defæcation with much flatus. Then there was a marked decrease in the distention and lessening of the nausea and vomiting. The patient was markedly relieved, though she continued to vomit at intervals during the rest of the day; she also expelled a small quantity of gas at intervals.

Fourth day. The patient vomited at intervals. Her abdomen was greatly distended. Oxygen was again passed into the intestine and a large quantity of gas was expelled; it continued to pass during the rest of the day, until the abdomen became quite flat. There was no further trouble with the passage of either gas or fecal matter. I was persuaded that the point of obstruction in this case was where the cyst was sewed to the abdominal wall. Before the oxygen was used the convolutions of the distended intestine were distinctly traceable through the very thin abdominal wall above this point.

Case IV.—Mrs. V——, aged thirty-eight years. Operation, myomectomy.

First day. The patient complained of severe pain in the abdomen, was nauseated at times, and had frequent eructations. At the end of the day, T., 100°; P., 74; R., 24.

Second day. There has been no passage of gas from the intestines. The abdominal pain increased, there were frequent eructations, but no nausea or vomiting occurred. T., 100.4°; P., 70; R., 20.

Third day. No passage of gas has occurred. The distention increased and severe abdominal pain was complained of. Oxygen was administered by the rec-

tum for five minutes, and a great deal of flatus was expelled promptly. The patient became more comfortable at once and convalesced without incident. I had determined to make use of the gas early when the symptoms began to indicate obstruction, and I made use of it in this case for that reason.

Case V.—Mrs. P——. Operation, abdominal section for ectopic gestation of two months or more. A long incision had to be made in this case, as adhesions of the omentum and intestines to the mass were firm and extensive. The sigmoid flexure was found much thickened directly over the mass, and it was with the greatest difficulty that the left tube, which was the seat of the trouble, could be dug out of its bed of adhesions back of the bladder and uterus and under the sigmoid flexure. It is somewhat difficult to understand how it got under the sigmoid flexure, but there it was. In the enucleation of the mass the serous and muscular coats of the sigmoid were torn in a triangular flap for an inch and a half. This was immediately repaired with fine catgut. The operation lasted an hour and a half. The patient became very weak during the latter part of it, and hypodermics of brandy and strychnine had to be given. Posterior drainage with gauze was used. The patient was put to bed with a pulse between 150 and 160. A pint of decinormal salt solution with an ounce of brandy was administered by the rectum. The patient rallied after this, but the pulse remained weak and rapid, 140 to the minute. She suffered from intense pain, and ♏ vi. of Magendie's solution were given. Vomiting and eructations occurred during the night, when strychnine gr. $\frac{1}{30}$ was given at intervals. An enema of salt solution and whiskey was administered and repeated after four hours. Constant vomiting of greenish fluid occurred. Hot water was given by the mouth at intervals.

Second day. Brandy and strychnine were injected hypodermically. T., 99.8°; P., 138; R., 28. The night was most uncomfortable. The pulse remained very weak and did not respond well to stimulants. There has been no passage of gas since the operation. T., 101.3°; P., 148; R., 26.

Third day. The patient was given hot water by the mouth frequently, and hypodermics of whiskey and strychnine at intervals of three hours. Salt solution and whiskey were administered by the bowel. Owing to the constant vomiting, she has retained no nourishment since the operation. No passage of gas or fecal matter has occurred. T., 103°; P., 146; R., 36, at 9:30 P.M. She feels very uncomfortable from the pain and distention. A small amount of flatus was expelled. Constant nausea and vomiting persisted. The patient is very weak, her pulse intermittent. Oxygen was administered by the rectum for ten minutes, and a large quantity of flatus was expelled. The nausea and vomiting were relieved, and she passed a more comfortable night. 6 A.M., T., 100°; P., 128; R., 28.

Fourth day. The patient responds very readily to stimulants. She vomited a little, after she had gone eleven hours without vomiting. She feels a little uncomfortable from gas. Oxygen was administered for ten minutes, and gas was expelled freely and frequently after this. No distention was observed. Oxygen was again administered for fifteen minutes, when flatus and fecal matter were expelled, followed by a thorough evacuation an hour later. T., 99.8°; P., 100; R., 24. There was no further trouble after this, and the patient was convalescing.

Conclusions.—I have been so impressed with the efficacy of the insufflation of oxygen in every instance in which I have used it, that I design to employ it always after abdominal section, as soon as any symptoms of obstruction begin to manifest themselves. By so doing I believe that many cases that might prove serious may be prevented from becoming so. They will at least certainly be relieved of much distress, and convalescence will be made much more endurable. As a prophylactic measure, I look upon it as of the highest importance.

Oxygen is easily obtainable, and is, in fact, always on hand in hospitals and sanatoriums. Its use is not attended with danger if ordinary care is observed. It should be introduced slowly, and, to make sure of this. should always be passed through water in a flask, which is made for the purpose and always accompanies the cylinder of oxygen. Used in this way it is perfectly safe. The patient will always indicate the moment it is desirable to stop. As soon as there is decided pain and feeling of increased distention the gas should be cut off. I have never seen the slightest evil effect from its use.

It not merely has the power to straighten out the intestines and open the lumen for the passage of gas and fecal contents, but serves as a stimulus to peristalsis. This was evinced in a number of cases in which not merely gas escaped, but large fecal movements followed immediately after its use. I am inclined to believe that with further experience it will be demonstrated that by its use active catharsis may be avoided.

Four of the cases detailed above were desperate, and in the last I am absolutely convinced that life was saved, that the insufflation made all the difference between life and death. In such a case as the one mentioned in the early part of this paper, in which on post-mortem a small intestine was found attached very slightly to an ovarian stump and so caused a fatal obstruction, I believe the insufflation of oxygen would have overcome the obstruction and saved the patient's life.

Inhalations of oxygen have been used in conjunction with iron in cases of anæmia, the claim being that in some way it helped the assimilation of the drug. Used by the bowel it must be absorbed to some degree and enter the general circulation, possibly not as oxygen, and serve in some way as a stimulant and tonic. But this is merely an after-thought. I made use of it solely for its mechanical effect.

A CASE OF ÆSTIVO-AUTUMNAL FEVER WITH UNUSUAL SYMPTOMS.[1]

By GEORGE L. PEABODY, M.D.,
NEW YORK.

F. H. P——, a carpenter by occupation, native of the United States, thirty-four years of age, married, was admitted to the New York Hospital on November 17, 1900.

His family history is negative. He has never been ill before, and has never had venereal disease. He is a moderate beer drinker. For the past two years he has lived in One Hundred and Fifty-fifth Street, on the East Side; for the nine years previously he had lived in One Hundred and Sixty-eighth Street on the West Side. During these eleven years he has only once been out of New York City; on that occasion, which was three years ago, he went to Pennsylvania and was absent four days. Last May he was suddenly seized with such severe headache that he was obliged to stop work, but he had no fever and has never had a chill. His headache came on suddenly, without apparent cause, about three o'clock in the afternoon, and continued to recur every day about the same hour, and usually lasted without intermission until eight or nine o'clock in the evening.

About the middle of June there was added to the

[1] Read at the meeting of the Practitioners' Society, December 7, 1900.

daily headache a severe attack of abdominal pain. This would start in the neighborhood of the umbilicus and radiate backward toward the left kidney, where it was especially severe. This pain has sometimes been relieved by walking, and is always immediately relieved by vomiting. He has no tendency to vomit; but the relief caused by vomiting is so great and so immediate that he has often deliberately irritated his fauces with his finger to provoke it.

These symptoms increased steadily in severity so that for the past seven weeks he has been confined to the house.

He has been treated in various ways without relief.

For the past week the pain has continued into the night, so that he has been unable to sleep. He has never had any bloody or coffee-ground vomitus, nor has he ever had any bloody or tarry stools. He thinks he has lost thirteen pounds since May. Of late his urine has been reddish in color and his frequency of micturition has increased. His appetite is good, his bowels are constipated. His chief complaint relates to the pain in his abdomen and head.

On admission at 3 P.M. his temperature was 103° F.; his respiration, 36; his pulse, 112. He was well nourished, in good general condition; his tongue was moist, pale, flabby, slightly coated.

Scars of wet cups were very numerous and of recent appearance all over his trunk.

His heart was normal; his pulse regular, of good force and tension. His lungs were normal. The liver was normal.

The splenic area of dulness was increased, and a firm, hard mass could be felt in the splenic region completely filling the left hypochondrium, but not extending beyond the ribs into the abdomen. This mass was tender to pressure and did not move at all with respiration.

His urine was normal in amount, and on the day after admission its record is this: 36 ounces, specific gravity 1.006, alkaline, light yellow, otherwise normal.

He had a large, loose stool in response to a dose of calomel. The electric pad was applied to the painful region with great relief, and sodium bromide gr. xx. was given. He slept but little the first night, although the heat of the electric pad gave him much relief. The abdominal pain was constant and interfered with sleep.

He was put upon milk diet. The following day his urine was normal, and it has continued so.

For the first three days his temperature fluctuated between 99° and 104° F.

On the second day his blood was examined for Widal's reaction with negative result, and for malarial organism with the result of finding a few crescents of æstivo-autumnal fever.

He was immediately then put upon quinine, gr. xv. a day and Fowler's solution, ♏ iii. after each meal, to be steadily increased.

The result of this treatment was the steady fall of his temperature. which reached the normal in twenty-four hours and has remained so now for more than two weeks. After twelve days the Fowler's solution had reached ♏ xi. to the dose. This caused flatulency. It was then discontinued.

Coincidently with the fall of temperature his pain steadily diminished, and in a few days entirely disappeared, so that he no longer needed the heat of the electric pad. In about a week he was out of bed, and for some days has been out of doors much of the time.

The cause of his pain is, of course, somewhat a matter of conjecture. As to the headache, that needs no elucidation: but why should his abdominal pains have been so very unusually severe?

The explanation which I offer is this: Probably his spleen is adherent to the diaphragm to such an extent as to interfere with its increasing in size to a normal extent under the influence of the malarial organism. We know how common these adhesions are between the spleen and adjacent viscera. It is often difficult to separate the spleen from the base of the left lung and from the kidney, even with every opportunity for careful dissection. If adhesions exist to the extent of preventing the spleen from enlarging in the usual directions of least resistance, may not its swelling have caused a traction upon the adhesions and upon surrounding viscera, and an alteration in pressure effect upon its own capsule, which may account for these unusual paroxysms of pain?

The position of the spleen, entirely filling the left hypochondrium and not extending beyond the free border of the ribs, is sufficiently unusual to suggest its being firmly adherent.

For two weeks the spleen could be felt as a hard, firm mass completely filling the hypochondrium. At present it has entirely lost this position. It has become movable with respiration and can be felt, as is usual in such cases, descending an inch or more below the free border of the ribs with a full inspiration. It is still very tender to pressure, but there is no such spontaneous pain as he formerly had. He sleeps well and is up and out of doors much of the time. The exact condition of this man's spleen is decidedly puzzling. It certainly was absolutely immovable for several weeks, being always distinctly palpable, and temporarily imposing upon several who examined the patient to the extent of causing them to consider it a tumor of the kidney. At present it offers nothing unusual to palpation in regard to its size, position, and mobility.

It is of interest that this form of malarial fever can develop in this immediate vicinity. It is but a short time since the belief was general among us that this did not occur.

INTESTINAL INDIGESTION.[1]

By A. P. STONER, M.D.,
DES MOINES, IOWA.

In the study of gastro-intestinal diseases one is struck with the paucity of literature upon digestive disorders of the small intestine. I find that some of the most eminent among modern writers on intestinal diseases, etc., fail to give consideration, even in a general way, to this important subject. Some authorities treat it under the head of diarrhœas, others include it under the head of intestinal catarrh, thus leaving the reader to believe that disturbances of digestion in the intestinal tract invariably lead to catarrh and diarrhœa. That this is not always the case will be one of the objects of this paper to prove.

In order that we may rationally discuss the pathological phenomena of intestinal indigestion, it is essential to have a clear understanding of the physiology of the normal process. Beginning, then, with salivary digestion, we will consider the action of ptyalin, the only ferment of importance found in the saliva. Ptyalin belongs to the class of unformed ferments, and acts only upon starchy foods. The starch molecule is a very complex one, and in the process of conversion into sugar it is known to undergo a number of changes, each of which represents a new body. Thus the first process of starch digestion consists in the liquefaction of the mass; the product being known as soluble starch or amylodextrin. As the action is continued, erythrodextrin is formed, and by the splitting of this molecule a body known as achroodextrin is created, which in turn is converted into maltose.

[1] Read before the Polk County Medical Society, December 4, 1900.

Saliva is an alkaline fluid, and starch digestion goes on best in an alkaline or neutral medium. Therefore, when the acid contents of the stomach are reached, the digestion of starches become more or less inhibited. Ptyalin activity does not entirely cease, however, until the maximum degree of acidity is reached,[1] usually about one hour after meals. This enzyme is not destroyed during the procedure. Indeed, it seems to have lost none of its hydrolytic functions by its gastric experience, for as soon as it comes into contact with the alkaline intestinal fluid it again becomes an active ferment possessed with all its original vigor.

Gastric Digestion.—The principal part played by the gastric juice in digestion is the conversion of proteids into soluble peptones. In the transformation of these bodies, several intermediate ones are formed, and are known as proteoses. The first step in the procedure converts the proteids into acid-albumin or syntonin. This body under the influence of pepsin undergoes hydrolytic cleavage, and forms the so-called primary proteoses, which consist of several proteid bodies, each of which in turn takes up water and forms a second group known as secondary or deutroproteoses, from which true peptones are elaborated. These changes are produced by the combined action of pepsin and hydrochloric acid. Pepsin possesses no activity outside an acid medium, and it will carry proteid digestion no further than the formation of proteoses and peptones. Recent investigators have shown that proteoses always exist in the mixture with pepsin, regardless of the amount of pepsin or hydrochloric acid.[2] We have now traced the process of digestion of starches and proteids through the stomach, and find that upon entering the intestine neither have been completely digested. The former have been only partly converted. Indeed, when the short period of mastication is considered, as well as the interruption of the digestive process in the stomach by the acid gastric juice, it should excite no wonder that the conversion of starch is incompleted in the stomach, and is finished only after the intestinal canal is reached. Here the starches are converted into dextrose by the amylopsin of the pancreatic juice, the ptyalin of the saliva, and invertase of the intestinal fluid. Many recent physiologists have undertaken to prove that the ptyalin ferment is of but little value, and that salivary digestion might be abandoned without disturbing the physiological process of digestion. They appear to lose sight of the fact that the enzymes of digestion, ptyalin included, always retain their activity even after they have completely fulfilled their digestive functions. Saliva is and should be continually swallowed, so that it may eventually pass into the intestinal tract. During the stimulus of a meal it is poured out in abundance, but does not engage actively in digestion until it comes into contact with the alkaline intestinal juices. Here, in company with the other amylolytic enzymes, it vigorously attacks the starch molecule and rapidly converts it into dextrose, etc. It may be remarked here that, so far as our present knowledge goes, ptyalin and amylolopsin are identical in their chemical composition and activity.

It remains now for us to consider the further action upon the proteids. The proteids upon entering the intestine are immediately precipitated by the bile, and those which have escaped digestion in the stomach are attacked by the trypsin of the pancreatic juice and reduced to proteoses and peptones; the difference between the action of trypsin and that of pepsin being, that under the influence of the former the proteids are reduced directly into secondary proteoses, all intermediate stages being omitted. This enzyme is also capable of carrying proteid digestion still further, and by the splitting up of proteoses and peptones there are formed a number of bodies, viz., leucin, tyrosin, nitrogenous bases, etc., the physiological significance of which is not understood. It is presumed, however, that this is a process of superdigestion, since it is believed that the normal condition for proteid absorption is in the forms of peptones and proteoses. They seem to be formed only when brought into prolonged contact with the latter bodies as in delayed absorption. Fats pass directly into the intestine, where they are emulsified by the bile and split into fatty acids and glycerin by the steapsin, in which condition they are absorbed by the lacteals.

The subject of absorption is still actively engaging the attention of physiologists. The laws of diffusion and osmosis, by which the older scientists undertook to explain absorption in the living animal, have been found to be very unsatisfactory. Heidenhain[1] has shown that solutions of nearly the same osmotic pressure as that of the blood were readily taken up and absorbed; even the animal's own blood serum was found to be readily absorbed. It was formerly thought that absorption of liquids took place between the cells. Recent observations have shown, however, that the cells themselves take an active part in the process, and a number of instances have been observed in which drops of fat were seen to be snugly ensconced within the cell protoplasm during the process of absorption. In the light of our present knowledge we may safely assume that absorption is due to an inherent property of the living cell, by which it not only takes up the products and passes them into the circulation, but, in the matter of proteids at least, it may be said that they are completely transformed within the cell substance while undergoing absorption. The proof of this assumption is found in the fact that neither proteoses nor peptones are present in the blood during digestion. Recent observations have shown that little or no food products are absorbed by the stomach. This organ is thus reduced to the rôle of digesting proteids, mixing food, and regulating the output to the intestine. Under normal conditions only small quantities at a time are admitted to the intestine.

From this brief study of the physiology of digestion and absorption we may deduce the following conclusions: (1) That all digestive processes are completed after having undergone primary treatment in the stomach. (2) That the absorptive process takes place chiefly within the small intestine. (3) That the facility of absorption is dependent upon the vitality of the cells which occupy the intestinal mucous membrane. According to Macfadyen, Nencki, and Sieber,[2] eighty-five per cent. of the proteids are absorbed by the small intestine under normal conditions, thus showing that the colon normally enters more or less into the absorptive process. That this is true is proven by the fact that the rectum is capable of absorbing raw proteids, such as egg albumen, milk, etc. This serves to explain why undigested food is not found more often in the fæces in cases of undoubted duodenal indigestion. The large intestine takes up the work of the small intestine, just as the latter does for a time in gastric disorders. It is now well known that the human subject will live an indefinite period after complete resection of the stomach, in which condition all digestive processes take place within the intestine. It may be stated, however, that if more than one metre of the small intestine is removed, serious symptoms will result,[3] and should the duodenum be

included in the portion removed, symptoms of inanition occur early, thus showing the importance of the intestine as a digesting and absorbing organ, especially the proximal end—the duodenum. Indeed, it appears that the duodenum is the most important organ of the whole digestive apparatus. This we would naturally be led to believe, since all the important digestive fluids are thrown into its upper portion. It should be noted that the intestinal secretion contains neither a proteolytic nor fat-splitting enzyme. But its sugar-splitting enzyme referred to is capable of converting the so-called di-sacharides—cane sugar, milk sugar, etc., into the more absorbable mono-sacharides—dextrose, levulose, and galactose. Its reaction is strongly alkaline owing to the presence of carbonate of sodium. It was formerly taught that the intestinal fluid was always of an alkaline reaction. This supposition was based upon the analysis of the intestinal and pancreatic secretions, and not upon the intestinal fluid as a whole.[1] Recent investigations show that under normal conditions the fluid in the duodenum is but faintly alkaline, and that the lower portion of the ileum is always acid. The acidity here is doubtless due to the action of bacteria. Were it not for the acid gastric juice being admitted into the duodenum, the reaction here would at all times be strongly alkaline. Intestinal and pancreatic secretion goes on continually, but the duodenum scarcely rids itself of its contents before another meal is taken, and the acid chyme is again poured into it, thus tending to neutralize it.

Gastric Hyperchlorhydria.—It is impossible for us to examine chemically a test meal from the small intestine as we would that of the gastric cavity, but we are hardly reduced to conjecture as to what really occurs in case the hyperacid contents of the stomach are admitted into the duodenum. The proteoses and peptones along with the pepsin are thrown down as a precipitate and are not further acted upon by the pancreatic juice; for this secretion acts only in an alkaline or neutral medium. The proteids are absorbable in these forms, and it is well that they should be, for when we come to consider the behavior of starches and fats under the condition of hyperacidity, we find that neither can fare so well as proteid products. Besides, it is to be remembered that in such a state of gastric disorder some of the proteids are admitted to the duodenum without having undergone change even into primary proteoses. Such products are with the greatest difficulty disposed of under a continued hyperacid condition. We have seen that starches and sugars pass through the stomach in a manner more or less unscathed. They cannot be further reduced in the acid medium now found in the duodenum, and the little absorption that takes place must be done in a gross state without complete reduction of their molecules. Fats cannot be emulsified in an acid medium, neither can they be split into fatty acids and glycerin, and must, therefore, be taken up by the cells and absorbed as liquid fat globules. It is needless to say that the last-mentioned substances are absorbed with much difficulty. Starch granules are passed through the entire canal without being absorbed. Some of the di-sacharides may finally be taken up, but not without much difficulty. Much of the fats will likewise pass out with the excreta. Indeed, even under normal conditions, particles of fat are found in the fæces, which have escaped absorption. It need scarcely be mentioned that the strain thus brought to bear upon the cell elements in their effort to take care of the unprepared products will, sooner or later, have a most deleterious effect upon them.

Over-Eating—Gluttony.—Normal duodenal digestion requires (*a*) normal secretion from the intestine, pancreas, and liver; (*b*) proper movement of the food mass; (*c*) normal or medium quantity of properly prepared food. When food is bolted in large quantities the stomach becomes overworked; the bulk is too great to be thoroughly mixed and digested; the chyme is passed into the duodenum only partly prepared; as a result of all these facts double work is thrown upon the latter organ. The duodenum might be able to withstand a temporarily increased activity if this were all that took place. If overeating is continued, however, the stomach finally gives way, and atony and dilatation ensue. Fermentation takes place, and hydrochloric-acid formation diminishes or entirely ceases. The nerve plexuses are eventually caught up in the dilemma, the result of which is sluggish circulation, secretion, and inhibited peristaltic action of the intestinal tract. Finally, there is failure to respond to the abnormal stimulus, and constipation along the whole digestive tract ensues. Should the gourmander eat a large variety of food, including fruits, etc., the artificial stimulus contained therein might be sufficient to keep up motion for a longer period until finally diarrhœa would follow. This is one of the first signs of an inflammatory process within the canal. Raw and improperly cooked foods likewise place an extra burden upon the duodenum. The cellulose covering of uncooked starch granules is not penetrated by any ferment. Defective secretion of the bile and pancreatic juice frequently causes duodenal dyspepsia. One of the offices of the bile is to promote peristalsis. Excessive secretion may, therefore, bring on increased peristalsis and consequent diarrhœa.

Intestinal dyspepsia is so often complicated with other diseased conditions that authorities have found it difficult to frame a set of symptoms which may be always referred to simple intestinal indigestion. Among the most prominent local symptoms may be mentioned a feeling of distress and an abnormal fulness referred to the hypogastric or gastric region, but without tenderness except upon deep pressure. There is a constant desire to eructate gas. The patient expresses the opinion that he would feel better if he could "belch," which, however, he is unable to do. One is led to infer that the cardiac orifice of the stomach is tightly closed, but if a tube be introduced it will be found that the stomach contains no gas whatever. The gas is all contained within the small intestine. There may be persistent flatulence, especially during the early stage; it is greatest, however, two or three hours after meals, at which time fermentation is most active. Constipation is the rule, but peristalsis and resultant diarrhœa may be excited by excessive bile secretion, organic acids, or marsh gas. Certain authorities have laid much stress upon the value of urinalysis in estimating the degree of intestinal indigestion. Urine containing an excess of urates and indican, with a trace of bile and uric acid, if accompanied with other symptoms of indigestion, may serve to clear up the diagnosis. All these, however, are more or less normal ingredients of the urine, some of which are the products of putrefaction within the large intestine. According to Van Valzah,[1] the diet test is the surest proof and is based upon the intolerance of starches, fats, sweets, and wines. Starches and fats escape undigested in the fæces; sugar sets up fermentation flatulence. There is at no time excruciating pain, but it finally becomes more or less continual. If the disease prevails for some time, mental depression is apt to appear. The patient becomes depressed, is more or less drowsy, especially during the digestive period, there is a tendency to melancholia, and the patient finally becomes incapacitated for mental or physical efforts. There may be palpitation of the heart, and the appetite becomes capricious. These

symptoms are many times referred to as cases of nervous dyspepsia. Just what connection simple intestinal disturbances may have with the pathology of the nervous system is a problem still awaiting solution. Since my attention was first called to the relation existing between neurasthenia and intestinal indigestion in the very excellent monograph by W. W. Van Valzah,[1] I have analyzed the gastric contents of a large number of my neurasthenic patients, and as a result have found them practically normal in the majority of cases. Especially is this true in the incipient stages. Nevertheless the patients continue to suffer from symptoms of gastric irritation. Gastric symptoms are present in nearly all cases of neurasthenia. To use the words of Dercum:[2] "Stomach diseases are the most common of the symptoms presented among the most distressing to the patient, and among the most difficult for the physician to treat." Many cases of so-called stomach diseases under such conditions, however, are purely those of intestinal indigestion. So constantly do we find gastro-intestinal disorders accompanying the neurasthenic state that it has led numerous investigators to seek for a cause in these phenomena. Since Hodge's investigations[3] have shown that nervous exhaustion is due to fatigue of nerve cells, the ardor of investigators along other lines has somewhat abated. The mere fact that the nerve cells are fatigued beyond the normal point does not satisfactorily explain all the symptoms of the neurasthenic condition. In neurasthenia, according to Dercum,[4] "various substances, the result of the metamorphosis in the nerve cell, are circulating in the blood." There is little doubt that there are toxic substances circulating in the blood of these cases, but why should they be a product of the metamorphosis of the nerve cell any more than an abnormal metabolism of other cells, or of toxic matter having their origin outside the body cells?

It has been shown that certain food products are with much difficulty absorbed in intestinal indigestion. It has also been stated that the individual enteric cells are responsible for the proper elaboration of certain food products. So long as the cells properly perform their function of taking up and preparing these products for tissue metabolism, the symptoms of dyspepsia are held in abeyance. But the moment that deranged functioning of the cells appears, gastro-intestinal trouble begins, and poisonous products are generated in the intestinal canal. The cells, in their effort to absorb and elaborate the gross products of gastric digestion, finally become incapacitated, and permit these substances, along with other toxic matter formed in the canal, to transude into the circulation as though the intestine were an inert animal membrane. The peptones themselves[5] under such circumstances would become toxic matter, and would circulate as such in the blood stream. The question may arise, Why are these poisons not separated from the nutritious elements and eliminated by the liver? The liver under normal conditions is doubtless worked to its full capacity in elaborating poisons, storing away and preparing new products for tissue regeneration, and when the intestine begins to give up its store of unprepared and toxic products, the circulation is soon loaded with the toxic elements of the system's own elaboration. Thus we have a condition of auto-intoxication which may, under favorable conditions at least, aid in producing nerve-cell exhaustion. That this assertion is more than probably true is proven by the experiments of Mosso.[1] This observer discovered that the blood of a fatigued animal when injected into an animal at rest produced characteristic symptoms of fatigue. These products of fatigue found in normal blood are not necessarily the result of metabolic changes of the nerve cells, although they may enter into its composition. They appear to me more likely to be the product of general tissue metamorphosis, since they react directly upon the nerve cell, which would hardly be the case if they were only a product of the nerve cell. However, until chemical analysis reveals the true nature of the blood in normal fatigue as well as in its allied state—neurasthenia—all hypotheses must stand subject to correction. Duodenal indigestion may exist without any connection with neurasthenia, and *vice versa*, for toxins sufficient to precipitate a pathological condition in the fatigued nerve cell may be elaborated elsewhere than in the intestinal canal. Upon this hypothesis, however, we may explain many symptoms found in both conditions, such as vertigo and insomnia, which many times may be overcome by cleaning out the digestive tract; palpitation and other heart symptoms, purely reflex or due to auto-intoxication.

In the very excellent monograph entitled "The Livers of Dyspeptics," by Dr. Emile Borix,[2] the author holds the alimentary canal responsible for numerous pathological conditions of the liver, including cirrhosis. If this hypothesis is true, one might safely venture a step further and very reasonably include the kidney. The increased activity of both organs necessary to meet the prolonged elaboration of toxic material is such that the way may be paved to chronic disease of either or both organs.

Pathology.—Numerous authorities have attempted to define the pathology of simple intestinal indigestion. However, in most cases, they seem to have described a condition very similar to, if not identical with, intestinal inflammation or catarrh. Cases of simple intestinal indigestion so seldom come to autopsy that the pathological anatomy is largely conjectural. According to Johnston,[3] the mucous membrane is swollen and hyperæmic, frequently being more severe in one part of the bowel than in another, being usually more intense around the solitary follicles and Peyer's patches, and on the tips of the valvulæ conniventes. In mild cases these follicles and patches appear as small white bodies standing out in bold relief against the injected zone surrounding them. In chronic cases, catarrh sooner or later is apt to intervene, masking the original picture, so that, when the cases are examined post mortem, evidence only of the catarrhal trouble is found.

The treatment of intestinal indigestion resolves itself into the consideration of the principles of dietetics. As in many other conditions, each case is largely a problem in itself, and must be treated individually. Most cases are caused by abnormal fermentation; therefore starches, sugars, and fats should be interdicted, and proteids in the form of lean meats given. However, excessive amounts of proteids may be the very cause of the disorder, in which case all albuminous substances should be expunged from the diet list, and some form of carbohydrates substituted. Predigested foods and artificially prepared enzymes have been used with varying degrees of success. My own experience has not been such as to lead me to place much dependence upon them. Drugs cannot cure intestinal indigestion, but they may be of inestimable value in overcoming the hyperacid condition and inhibiting the action of bacterial fermentation.

On the whole, our better judgment must guide us in laying out the best line of treatment to be followed in each individual case.

ON THE EFFECT OF TOPICAL APPLICATIONS OF EXCESSIVE STRENGTH AND IMPROPER DIET AND HYGIENE IN PROLONGING AND CAUSING SKIN DISEASES IN INFANTS AND YOUNG CHILDREN.[1]

By S. SHERWELL, M.D.,

CLINICAL PROFESSOR OF DERMATOLOGY, LONG ISLAND HOSPITAL MEDICAL COLLEGE; CONSULTANT PHYSICIAN, LONG ISLAND AND BROOKLYN HOSPITALS; MEMBER OF THE AMERICAN DERMATOLOGICAL ASSOCIATION AND THE NEW YORK DERMATOLOGICAL SOCIETY, ETC.

The subjects indicated by the title have for many years been of great interest, not to say aggravation, to me, and I hope their brief consideration now will be of interest at least to the reader. I have purposely inverted the usual order, commencing with the remedial end, so to speak, instead of the causative.

My almost daily experience, certainly so during the busier months of the year, in both private and clinical practice, is to have babies and young children brought to me, who have already been for varying lengths of time subjected to treatment so manifestly harsh and improper that it sometimes has seemed without excuse.

The majority of these patients, I may say, are suffering from skin troubles of an eczematous character, for it may be here observed that the percentage of eczemas in childhood is greatly in excess of that of adults, I should say as fifty per cent. to thirty per cent. in adults, the usual statistical average, and in explanation of this one has to consider the much greater exposure of grown people to accidental dermic lesions, degenerative trouble, etc. Other reasons will be made evident, as I believe, later on.

In these infantile cases, then, I find too frequently, from the history, that a frank, mild enough eczematous inflammation, in the beginning needing nothing more for its relief than a protective dressing, or soothing salve, or lotion, has, from the irritating character and strength of the remedies applied and given, developed into a highly dermatitic condition; or, even worse, has assumed a chronic form from persistence in the various irritant applications, and thus has become much more difficult to relieve or cure.

The stronger topical applications are ordinarily the chiefest sinners in bringing about this state of things, though they have been possibly officinal and classical in every sense; but they would seem to have been employed without reference to gradation in strength, or consideration in relation to age, type, diathesis, constitution, or complexion; and also when, possibly, the first agents used have failed to benefit, still stronger applications "good for eczema" have been employed. By the bye, this expression, "good for eczema," one hears so often I would like to attack just here, and would like to be understood as insisting that there is *per se* nothing "good" for an eczema, any more than a color, any one or more colors are good for a picture. Again, almost anything may be good for a particular form, or a particular state of an eczematous lesion. The judgment that sees and knows that, for instance, an unguent strong enough and stimulant enough for a light blonde, and possibly strumous child, will hardly faze or affect those of the brunette type with thicker skins, if not hardier temperaments and constitutions.

The pharmacopœia, rightly enough, gives about the average strength of preparation for the average individual—the young adult may be taken as the type; but I am free to state my conviction that there is not one of such compounds which could and should not be graduated down with benefit and great advantage, as to strength, to suit most cases in children. I even think the benzoated oxide-of-zinc ointment, unmodified, is too strong for general and free use in children, good as it is when appropriately toned down with cold cream or some other lenitive.

The mercurial salves and preparations are especially sinned with; almost all, I think, are far too strong for ordinary use in the class to which I refer. One certainly finds words of precaution attached to some of the formulas of these in the pharmacopœia, as "this is a decided stimulant," etc.; but I think hardly enough stress is laid on the subject.

Combinations of some of the extra-official drugs, in salve or lotion form, as for instance the following: chrysarobin, iodoform, thiol, ichthyol, salicylic acid, resorcin, the tars of various kinds, etc., in any great percentage are almost always unadvisable, and sometimes very injurious in their effects, unless the indications are pretty plain and the skin is pretty tough; they, when used, should be tried at first in very great dilution, etc. I have been surprised sometimes to see in well-known and really excellent dermatological works certain formulas for preparations of this last class recommended, which I would not dare to apply to any white American child; I was about to add, adult. These recommendations and formulas occur more often in foreign treatises on the subject than in our own, I think, but even they are not exempt. One fact I have not seen noted elsewhere, but which is, according to my experience, certainly true, and that is, that even unguentum petrolatum or vaseline (and this of the purest) is, in a fairly numerous percentage of children, irritating and not well borne; so that, even when it has been used for protection and mild inunction only, a distinctive dermatitis has been caused. There seems to be a certain idiosyncrasy in this matter in about ten per cent. of people, for the effect is not confined to children. When, however, a stimulant action on the skin is called for, as in psoriasis of young children and others, it makes an excellent base, better perhaps than any other, on account of its non-rancidifying qualities, so that it is extremely useful in applications that are to remain for some length of time. I would remark here, parenthetically, that a psoriatic skin is always a tough and resistant skin, and usually the covering of a tough, healthy body, so that liberties which would be resented in a delicate integument are not noticed in this condition.

I cannot, of course, in the short time I purpose to occupy, go on and criticise the whole pharmacopœial list "seriatim"; it would anyhow exercise your patience too much, for no corresponding good, but I would simply, as the gist of my experience of considerably over a quarter of a century, recommend to all, first the milder measures, and the necessity of considering the individual case as to diathesis, etc., as above given, the exact state of the lesion itself, duration, etc.—these all having a direct bearing on the treatment of any particular case. A relatively newly apparent, acutely inflammatory, possibly weeping lesion always demands decidedly less stimulant treatment than a scaly, infiltrated, indurated, or almost œdematous condition.

For a few moments now I would like to consider some of the most apparent and common errors of diet and hygiene. In order to do this more clearly and perhaps avoid repetition, it would be well to divide the children into three classes—class I., those at the breast or bottle, up to the eighteenth month; II., those from that age up to pretty nearly three years, when primary dentition is about accomplished; III., those of that age and, say, up to about the sixth year.

[1] Read at the meeting of the Kings County Medical Association, November 13, 1900.

While considering the case of infants of the first class, I am tempted to transcribe, and will, with your permission, read a few paragraphs from an excellent letter to the MEDICAL RECORD of October 20, 1900, by Dr. John B. Huber, of New York, which coincides exactly with my experience as to overfeeding and improper clothing of infants, especially in summer:

"The causes of disease especially manifested at these examinations were irregularity in feeding, and overclothing. As regards the feeding the following are specific instances: One child, who (so the mother said) was suffering from 'stomach trouble,' held in its fist most of a cracker. Its mouth was full of half-masticated food. It was given food 'whenever it wanted something to eat,' so that its digestive apparatus was almost never at rest. The baby was thin, weazened, and had a clammy sweat on its face. It looked senile. It was bottle-fed; and the bottle was given it 'whenever it cried.' One child during the inspection gorged himself upon a huge cruller; the mother explained, 'I keep him quiet that way.' Several children lunched without intermission all the while they were seen.

"As regards the clothing: On one very hot day the suffering from over-much clothing was especially conspicuous. They (the babies) were almost never without heavy 'belly-bands.' Prickly heat was very rife among them. Almost all of them cried piteously, no doubt because they were over-clothed. They were reeking with perspiration. Six thicknesses of clothing, more than half of which were woollen, were the average."

But now, for instance, we will take an ordinary healthy babe, fed from the breast in the most normal way and by a healthy mother. The infant bears every sign of being well nourished (too well nourished). That particular baby may or shall have, when brought to you, an eczema of intense character, on either and more probably on both cheeks, and often extending behind the ears, etc.; no known cause. Its bathing and care are seemingly all that could be asked for. Now in this class of cases I find most frequently that they are over-nursed; at any sign of irritation or disquiet on their part, they are given the nipple, and additional food is thus given to a probably already surcharged "prima via," instead of what they most need, especially in summer, and cannot ask for—a drink of sterilized water, slightly alkalinized, and, if you like, slightly sweetened. This is so common during the summer months that I have long been thinking about writing a little paper on this subject alone, feeling so strongly about it as I do. The poor little things, perspiring freely, too much clothed as they usually are at that season, possibly foul clothing too, necessarily become fretful, then in goes the food, instead of what is wanted—some water (*a fortiori* it can be seen how much more this applies to bottle-fed children)—thereby irritating the gastro-intestinal tract and increasing the already irritated condition of that analogue of the skin, the mucous membrane, and thus, as I believe, by reflex action irritating the skin itself. This is the history, and this the etiological factor, I am convinced, of many eczematous efflorescences, and most certainly I am convinced, too, that it is plainly a factor in their continuance and in the persistence of the same.

To turn from the baby to the mother, whose milk may be the cause of this irritation of the mucous membranes, I may ask, How often does the average medical man question her as to her possible diathetic conditions, or habits; is she rheumatic, constipated, dyspeptic? All of which, though she may be of robust appearance, have as conditions much bearing on the lacteal secretion and consequent nutrition of the infant, and all of which conditions certainly (and some others I will not mention) can be corrected by treatment, and should be. I think the use of stimulants and malt liquors, though so frequently recommended, is injurious, as a matter of fact, to almost all nursing women; it certainly is when a lithic-acid diathesis can be made out.

A curious thing I find, and one that is said to be recommended by some physicians, is dread and avoidance of a daily bath to the parts affected of the children, and sometimes to the whole body of the child so suffering; this seems to me idiotic—to allow the nasty rancidifying, butyric-acid decomposition of a grease that has been applied for days or longer, and that is only removed by the attrition of the clothing, seems absurd. A gentle washing should be given once daily; I do not want, of course, the skin macerated therewith; it is better, too, to make the water blandly alkaline with borax or soda and bran bag, so as to take away from the water its endo- and exosmotic properties; and after that to renew the sweet and clean application of whatever kind is necessary. As to underfed and strumous and possibly luetic babies, the indications are so plain that I will not presume to take up your time with advice, and so will go on to the consideration of what I call Class II.—those from the latter mentioned age to two and one-half to three years old. They generally have a wider range of distribution of the lesion, on the flexures it may be; anywhere, in fact. The question of diet here again comes up, and to the question to the parent, What do you give them to eat? the reply will often be, Almost everything. The result from the same cause—the gastro-intestinal irritation causing the eczematous reflex which the child had escaped during the nursing period, in which the child has been normal sometimes, and this possibly not so much from care as from carelessness of the mother during that time. I do not deny that the dentition process seems at times to have much to do with the production of eczematous manifestations in infants, but consider here that the chain of cause and effect is pretty much the same—irritation of the buccal and gingival mucous membranes, irritation and change of secretion of the salivary and other glands, causing indigestion and the reflex troubles of the skin, as aforesaid.

Restriction of the diet of these children is, of course, the first thing in order, stopping the dosing with tea, coffee, and what not; mild treatment with alteratives and corrective salines (the mouth secretions are almost invariably quite acid in these cases). As to the treatment of skin itself, it is almost always in need of bland and soothing, and slightly alleviative (mercurial) application in these cases.

Class III.—children from two and one-half to six years. Here again I might recapitulate the directions given already in respect to the class immediately preceding, and to reinforce them; for here the grosser forms of malnutrition come in, and again, in my belief, are followed by the same results, from the same causes. Unripe or decaying fruit, excess of sugar or sugared foods, abominations in the shape of candies, etc., may be named and deprecated as causes. One always should have a suspicion of ascarides in this group of cases.

Most of my remarks heretofore have applied to the children and parents of the poorer and presumably less intelligent classes, but in this group the more favored children of those of larger means are not exempt. Frequently, among this last-mentioned class, a great excess of food, or so to speak "forced diet," is very much in vogue, the aim being apparently to make a big, fat child by constant nutrition. These children are so stuffed that they hardly know what it is to have a healthy appetite, yet led by custom, and the fact of well-prepared food being laid before them at stated times, they eat inordinately, at least it may be called

so, in relation to the wants of their systems. They are liable to become fat, florid, and dyspeptic anæmics, irritation of their "primæ viæ" results from repletion, and again follows the reflex. They are often hard cases to treat, the economy seems to be torpid and sluggish, a little moderate starvation is good in these cases; they will often stand more stimulant applications to the skin than some of the other cases, or groups of cases, and alteratives, such as a little hydrargyrum cum creta, are very useful. In examining the urine of this overfed class of children, the pampered ones of rich and overanxious parents, I have often found a very noticeable amount of sugar. They had not, of course, true diabetic glycosuria, but simply interference with perfect metabolic action from repletion and its corollaries, and I believe this glycosuric condition has often predisposed to, or caused the eczematous tendency or manifestation. In other cases of the same sort the urine would be found loaded with pale amorphous urates, in still others the phosphates would be altogether out of normal proportion, so that in various ways the system would be found, according to the particular diathesis of the child, to be so interfered with by overnutrition that it and its consequences would be in any case a predisposing if not originating cause of an eczema and as unquestionably a perpetuating and prolonging factor.

Much might also be said regarding the clothing of this class of children if it did not unduly prolong these remarks. It is not, of course, reeking and foul, as is often the case in those of poorer circumstances; but in summer it is frequently too warm and overloaded with stiff starched frills and furbelows that render the child fretful and uncomfortable, and that interfere with any application made. From a common-sense point of view, how much better in every way would be the comfortable warm belly-band or loose and soft woollen undergarment, with something lighter and unstarched as an outergarment. I and you have doubtless often seen children tortured with their stiff pointed lace caps and collars, pricking into them with every movement, and as it were goading them to desperation; and yet these same children shall be accompanied, tended, and cared for by women in the nurse's (either trained or untrained) dress, which I take as the acme of costume for a woman in appearance as well as comfort.

These remarks would seem to me already too long further to consider specific remedies, or to go into hygiene further, except in the most general way, but I may be allowed to express my opinion in general as a summing up. First, I believe that while each and all of the infant foods so extensively advertised and used may be of use in particular cases, I still think that cow's milk appropriately diluted, sterilized, peptonized, and rendered mildly alkaline, as found necessary, is always about as good as anything that can be employed as food for them.

I must say, too, that in internal treatment of not only skin diseases, but in all those in whom perverted metabolism and its results occur from abnormalities of secretion in the primæ viæ, my great preference, instead of castor oil, rhubard and soda, and other laxatives and mild astringents, is the hydrargyrum cum creta in fractional or other doses; when necessary a little pulvis ipecacuanhæ compositus being added. Whether diarrhœa or the opposite condition is present, this remedy almost always comes in. How to explain the beneficence of its action is not so plain. Of course, it would be evident in luetic infants, and those specifically marasmic (I find this latter condition very common, and I regret to say often unrecognized), but the remedy in any case acts as mild stimulant of, and aid to proper secretion in, the glands and guts, and is as certainly to a large extent disinfectant and antiseptic, so that a catarrh of the mucous membrane, and incidentally a catarrh of the skin, which eczema is, is thereby benefited.

THE CLINICAL VALUE OF THE HEART REFLEX.

By ALBERT ABRAMS, A.M., M.D.,

SAN FRANCISCO, CAL.,

CONSULTING PHYSICIAN TO MOUNT ZION AND THE FRENCH HOSPITAL.

Two years ago[1] I first directed attention to a phenomenon before undescribed, which I called the heart reflex. At that time I ascribed to it little clinical value, regarding it solely in the light of an interesting observation. Since then I have devoted considerable attention to this reflex with the object of ascertaining its practical application. The results exceeded my expectations. The heart reflex can be observed only with the Roentgen rays, the fluorescent screen approximating the anterior chest wall. The reflex is especially pronounced in children, and is best seen in adults with thoraces scantily furnished with musculature and panniculus. If we irritate the skin in the precordial region by vigorous rubbing with a blunt

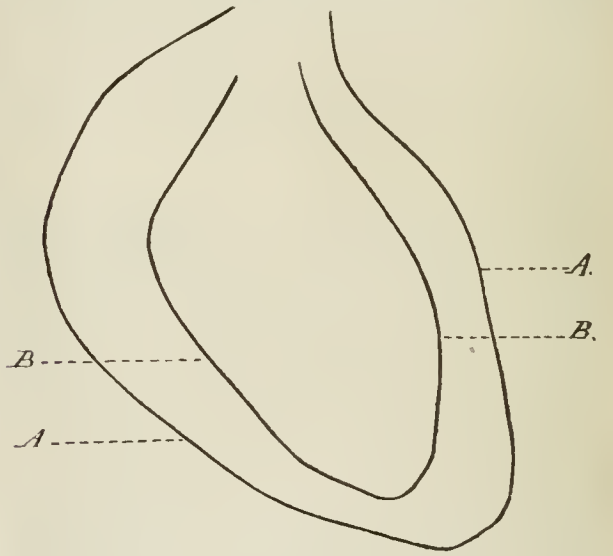

FIG. 1.—Heart Reflex in a Boy Aged Eight Years. Duration of reflex, two and a-half minutes.

instrument, a contraction of the myocardium is observed. The myocardial contraction is, as a rule, more manifest in the left than in the right ventricle. The contraction thus induced is not sudden and of momentary duration as I described in my original paper; on the contrary, its duration in children, on whom most of my observations were made, is not less, as a rule, than two minutes, and furthermore the myocardial recession continues even after the source of cutaneous irritation is removed. The degree of myocardial recession (heart reflex) varies greatly. In some persons it is scarcely perceptible, while in other individuals the heart may recede fully an inch on either side upon the first application of the cutaneous irritant. The above illustration will show the degree of myocardial recession (line *B*) after cutaneous irritation; *A* representing the normal outline of the heart drawn on the fluoroscope.

This illustration is an exaggerated one, for, in the many examinations made by me, I have never been able to induce so marked a reflex. It is strange that in not a few instances the myocardial recession, although rarely absent when observed with a good *x*-ray apparatus, is but slightly marked. For this vagary I am unable to account, occurring as it does in individuals with apparently healthy heart muscle.

[1] MEDICAL RECORD, March 26, 1898.

In Fig. 2 we note a rough reproduction from the fluoroscopic picture demonstrating slight myocardial recession confined solely to the left vetricle; *A* representing the cardiac outline before and *B* after cutaneous irritation; *C* is the upper hepatic line.

In my original paper I advocated the rhigolene or ether spray as the best cutaneous irritant; since then, however, I have tested different modes of cutaneous irritation for clinical purposes, and I am now constrained to conclude that friction of the skin by means

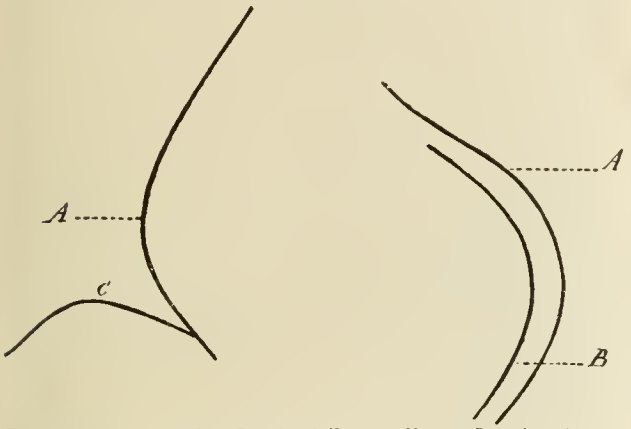

Fig. 2. Heart Reflex in a Boy Aged Fourteen Years. Duration of reflex, fifty-five seconds.

of a rubber (the ordinary pencil eraser is suitable) is the best cutaneous irritant for provoking this reflex.

The nearer we approximate the precordial region and the more vigorous the cutaneous friction, other things being equal, the more pronounced is the heart reflex. The latter reflex may be slightly discharged, even though the cutaneous irritant be applied to remote parts of the body. In individuals with dilated hearts the reflex is very evident and of much longer duration than in healthy hearts. Before referring to the practical value of the heart reflex let me direct attention to another phenomenon which I have called the lung reflex.[1] This phenomenon can be observed without the aid of the Roentgen rays. If the skin of the thorax is irritated artificial lung dilatation ensues. The degree of the dilatation varies with the severity and extent of cutaneous irritation. Vigorous rubbing of the skin of the precordial region is sufficient to obliterate the area of superficial cardiac dulness. The same statement applies to the spleen and in part to the liver. If irritation of the skin is made anywhere on the chest corresponding to the lower lung border, percussion will show, say in the axillary line, a descent of the lower lung border fully 6 cm., a degree of dislocation even exceeding that obtained by forced inspiration. Aside from its percussional recognition, the appearance of the lung reflex by means of the *x*-rays is distinctive. Coincident with the discharge of the reflex, the lung area implicated shows increased brightness lasting from a few seconds to two minutes, the lung after that time resuming its normal skiascopic appearance.

In a previous paper[2] I espoused the theory that the real factor involved in balneo- and mechano-therapeutics (Schott) was dependent not on the baths and exercises as such, but owing to the cutaneous irritation provoked by these manœuvres. In accordance with this theory, I have, since this contribution, employed vigorous cutaneous friction by means of hand-rubbers obtainable at any drug store, after immersion of the patient in a warm bath for fifteen minutes; the warm bath augmenting the sensitiveness of the skin. By this simple and expeditious method, in chronic heart disease, I can adduce results emulating the conventional Schott method. Relief of dyspnœa follows, there is reduction in cardiac volume, besides a marked reduction in pulse rate with increase in volume and force.

The following conclusions may be formulated in reference to my method of treatment and that of Schott.

1. Lung dilatation follows the exercise and bath treatment, the lung acting as an excretory channel for the overburdened heart.

2. The cause of the lung dilatation is dependent on cutaneous irritation induced by the exercises and baths.

3. A decrease in the volume of the heart also ensues and is likewise provoked by cutaneous irritation.

In explanation of the heart and lung reflexes, we all recognize the influence of the skin in physiological and pathological conditions. According to v. Preuschen, stimulation of the respiratory centre is greater through the cutaneous nerves than through the vagus branches to the respiratory organs. In animals which have been made apnœic, the application of cutaneous stimulation (cold water) induced stronger respiratory movements, and he concludes that mechanical cutaneous stimulation by flagellation, cold water, or the electric brush, is of the greatest value in stimulating the centre of respiration.

The centre for the inhibitory nerves of the heart is stimulated reflexly by centripetal nerves. In support of this physiological axiom we need only recall the "Klopf-Versuch" of Goltz, which demonstrates that striking the abdomen in animals will inhibit the heart's action.

I regard the heart reflex test as pathognomonic and far exceeding all other methods yet recommended in differentiating a dilatation of the heart from pericardial effusion. This is conceded to be one of the most difficult problems for the clinician. If, in a given case of increased cardiac dulness which has been carefully outlined, we vigorously rub the skin of the precordial region by means of a rubber, and note after two minutes (the time necessary for the abolition of the lung reflex) a reduction in cardiac dulness, we are justified in concluding that we are dealing with cardiac dilatation and not with a pericardial effusion. Let me illustrate my meaning by reference to Fig. 3. This is a rough reproduction of a reaction obtained in a young man with massive dilatation of both ventricles. *A* represents the percussional area of the heart before cutaneous friction. The dark area represents the area of cardiac dulness after cutaneous irritation, and is caused not wholly by a reduction in cardiac volume,

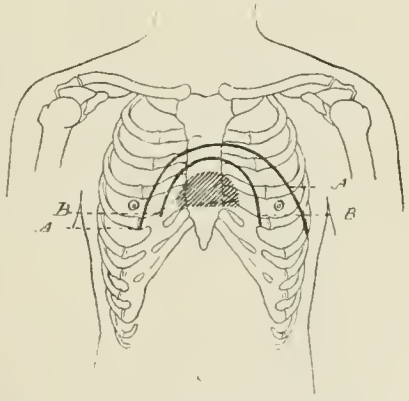

Fig. 3.—Illustration of Heart Reflex in Cardiac Dilatation. *A*, Percussional area of dilated heart. Dark area, percussional area after cutaneous friction; *B*, percussional area, showing heart reflex persisting after abolition of the lung reflex.

but also by the lung reflex which induces the lung to encroach on the area of cardiac dulness. After waiting two minutes, a time exceeding that necessary for the lung to recede, the percussional area *B* is obtained, which actually represents the decrease in the

[1] New York Medical Journal, January 13, 1900.
[2] The Medical News, January 7, 1899.

cardiac area (heart reflex). If pericardial effusion were present there would be some evidence of the lung but not of the heart reflex.

We have yet to learn the value of the heart reflex as an index to the condition of the myocardium.

S. W. Corner Van Ness Avenue and California Street.

A CASE OF PERFORATING GASTRIC ULCER.

By A. B. ATHERTON, M.D.,
FREDERICTON, N. B.

In the Medical Record of January 5, 1895, I reported a case of perforating gastric ulcer successfully operated on, and I now have the pleasure of recording my second operation for the same disease, which was attended with a like result.

As is well known, it is essential in this complication of gastric ulcer that a diagnosis should be made very early, and prompt surgical treatment be instituted, in order that the patient may have a fair chance for recovery, and for this reason the surgeon who does some general practice and has the good fortune to be called at once to such a case has the advantage over the more purely consulting surgeon, who is more apt to be called in somewhat too late to give the best result from operation. In both my cases I operated within twenty-four hours from the commencement of the acute symptoms, the exact time being in the first fifteen and in the one now reported only ten hours.

At 1 A.M. on March 26, 1899, I was hastily summoned to see M. D.——, aged sixty-two years, on account of a severe pain in the belly, which had suddenly come on about an hour before. On inquiry I learned that he had had dyspepsia for fifteen years. He had to be very careful about the food he ate, because of pain and sometimes vomiting. He had never vomited blood. His mother died from "cramps" at fifty, after an illness of twenty-four hours. There was nothing to indicate any hereditary tendency to gastric disease unless this was.

He had been travelling by rail and water for a few days, and his stomach had not felt well. He had not eaten anything for twenty-four hours except a little porridge the previous morning.

I found him sitting on the side of his bed, leaning over forward to relieve the agonizing pain in his abdomen. He could not lie down. He had not vomited. His abdomen was very tender and rigid, especially at its upper part. The left rectus seemed rather harder than the right. The belly was somewhat tympanitic, but there was no manifest distention, and liver dulness was present. P., 70; T., normal.

I at once gave a half-grain of morphine subcutaneously. A short time afterward he vomited over a quart of dirty, dark fluid with some oatmeal in it. No blood was noticed. The morphine required to be repeated in half an hour, and a third dose was given at 3:30 A.M. After this he became fairly easy, but preferred still a sitting posture.

I visited him again at 6:30 A.M. He had taken in the mean time by the mouth a fourth half-grain dose of the morphine, and had slept half an hour. He was found now lying down in bed. The belly seemed much the same as at my first visit. Pulse and temperature likewise were as before.

At 8 A.M. he was removed in a hack to the General Hospital, and was operated on at 10 A.M., the usual preparation being made to insure antisepsis.

The anæsthetic was given by Dr. McLearn, and assistance rendered by Mr. Roy Van Wart, medical student.

A median incision about four and one-half inches long was made above the navel. When the peritoneum was opened a puff of gas escaped, and some bubbles were also seen. Then some turbid serum flowed out from the right side of the upper incision, and some mucus and lymph were seen there. An opening of the size of a lead pencil was found on the anterior surface of the stomach, near the pylorus, with nearly black mucous membrane pouting out of it. The hole was closed by two rows of Lembert's silk sutures. Considerable induration was felt around the opening. Sponges were used to clean out parts beneath the liver and the right lumbar region. Some strips of iodoform gauze were placed here for drainage, their ends being brought out of the upper end of the wound. The rest of it was closed by fish-gut sutures. Iodoform and bichloride gauze dressings were applied.

12:30 P.M.: He feels much better and has slept considerably since the operation. He is rather lethargic. The pupils are much contracted. P., 68; T., 96.5°.

March 27th, 9 A.M.: The dressings were changed last night and at the visit; the temperature ran up to 100° in the night; it was 99.5° this morning. He had gr. $\frac{1}{6}$ morphine last evening and rested fairly well.

March 28th, 9 A.M.: Temperature normal. One piece of iodoform gauze was removed from the abdominal cavity. No vomiting has occurred since the operation.

March 29th: The rest of the gauze was removed from the abdomen. Some fish-gut sutures, which had been left loose at the site of the strips of gauze, were now tightened. P., 70; T., normal. The bowels were moved well yesterday by enema.

April 6th: All is doing well. The sutures were all removed. The wound is about healed.

April 15th: He has had heartburn at times, for which soda and bismuth have been given. Also care was used in diet. The pain in the epigastrium was quite severe to-day and he vomited a pint or more of dark liquid, with considerable blood in it. Morphine gr. $\frac{1}{8}$ given hypodermically relieved him. He is to have only milk and lime-water, and curds.

April 20th: He is doing well, and may get out of bed. He asks for and may have the whites of two or three eggs per day, as he says these always agree with him.

April 25th: He is discharged from the hospital, and left for his home in Grand Manor a few days afterward.

On March 3, 1900, I received a letter from the patient's wife, informing me that he had just died. She said he seemed to get on well until about Christmas when he began to be troubled again with his stomach, and vomited a good deal of bloody mucus for a week. Then he improved for a time, but later on had "pleurisy and a trouble with his lungs and never regained his strength."

Hæmophiliac Joints.—Tilmann describes a case of this somewhat rare lesion occurring in a man of twenty-two years, whose previous history and antecedents did not point to any blood dyscrasia. A slight trauma was followed by extensive painless swelling of the left knee joint which kept relapsing after apparent recoveries during a period of three years. Tuberculous disease was excluded by the tuberculin test, and a diagnosis of arborescent lipoma made. Operation was accordingly decided on, with the remarkable result that thirty-six soft elastic bodies, varying in size from that of a pea to that of an almond, were removed. The patient recovered well from the operation, but the next day the joint was found distended with blood and all attempts to check the hemorrhage, which apparently consisted in extensive capillary oozing, were fruitless, the patient finally succumbing three weeks later, completely exsanguinated. The bodies removed from the joint were found to be fibrin clots, which, as they were

almost wholly devoid of red-blood cells, were assumed to have resulted from the chronic plastic inflammation set up in the synovial membrane. The case is interesting as illustrating the care which must be exercised in excluding the possibility of this lesion before operating on obscure joint affections.—*Deutsche Aerzte-Zeitung*, October 1, 1900.

A New Symptom in Epilepsy.—Carlo Ceni reports a curious fluctuation in the bodily temperature of epileptics, which he considers of sufficient constancy and importance to merit a place in the symptomatology of the disease. The phenomenon in question is a very marked temporary drop in temperature occurring at various times of the day or night. The drop may be of from one to five degrees and last from a half to one hour. The phenomenon has all the characteristics of an epileptic crisis, which does not come to the consciousness of the patient. In some instances it was observed three or four times in the twenty-four hours, but more often it appears periodically at intervals of several days or weeks. There is no apparent connection between the occurrence or the frequency of these variations in temperature and the severity of the disease itself, neither do they appear to stand in any relationship to the typical epileptic seizures.—*Centralblatt f. Nervenheilkunde und Psychiatrie*, October, 1900.

Some Thoughts Relative to the Etiology of Degeneration.—Charles E. Woodruff defines a degenerate as an abnormal man whose variations or stigmata are developmental and due to an unstable nervous system. The variations from the average may also be due to diseases resulting from an unstable nervous system, such as rickets and the deformities of infantile paralyses. So long as we recognize that the essential defect of the degenerate depends upon the faulty composition of the substance of the nerve cell or its ancestor, the germ cell, although the character of the defect may be absolutely unknown, we are justified in using the unscientific term, nervous instability. We are perfectly aware of its indefiniteness, yet until the pathologist shall have taught us all about the composition of the nerve cell in health and disease, we can find no other term which will define a condition which, however, we know to exist. Marvellous results, however, follow from the proper care and raising of the children of degenerates. Children of the slums taken early, fed and raised in honest families, as a rule become normal citizens in spite of terribly degenerate parentage. We read of the results with delighted astonishment. This theory may also do away with that fatalism which condemns degenerates and their offspring as hopelessly incorrigible, and which gives rise to the various absurd proposals for preventing their reproduction. Efforts at regeneration will take the place of nature's brutal methods of ruthless destruction of the least fit, as it is the rule for civilization to preserve and make useful that which was formerly destroyed by nature with reckless prodigality. Unfortunately the adverse environment of an abnormal intra-uterine life may be so disastrous that no subsequent care can repair the damage already done, so that degenerates will be encountered so long as man exists.—*American Journal of Insanity*, October, 1900.

Popliteal Aneurism Cured by Digital Pressure of the Femoral Artery.—C. A. Hamann thus writes of his experience with a recent case: The patient was a colored man aged forty-two years. Some four or five weeks before coming under observation he noticed swelling about the knee and pain in the popliteal space when walking. On examination I found a very distinct aneurism of the popliteal artery, about as large as a hen's egg. The characteristic symptoms of aneurism were present with the exception of a bruit. There was œdema of the leg, and the superficial veins were distended. The arteries were atheromatous, the aorta was dilated, and the left ventricle was hypertrophied. There was no history of trauma, the pain and other symptoms coming on gradually and steadily increasing. The treatment used was digital compression. The services of a number of medical students were secured, and compression of the superficial femoral artery was kept up for thirty-six hours. It was necessary to use some morphine. Four hours before the compression was stopped there was still pulsation in the sac. At the expiration of thirty-six hours the pulsation had ceased. A splint was applied for three or four days, and in a week the patient was allowed to get up. He now limps slightly, but extension is almost perfect. A solid mass can be felt in the popliteal space. The swelling and œdema have disappeared.—*Cleveland Journal of Medicine*, November, 1900.

Primary Sarcoma of the Liver.—Antonio Cesario Sèmel reports a case which demonstrates the fact that a primary sarcoma may develop in the liver, even in adult life. It also demonstrates that the structure of sarcoma is not always alveolar, nor its origin perivascular, as is usually the case, but that it may be developed directly from the connective-tissue trabeculæ of the liver, having the form of round or polymorphous celled sarcoma in the young, actively proliferating nodes, to be later transformed into the typical fibrosarcoma.—*Archivio per le Scienze Mediche*, vol. xxiv., No. 3.

On the Use and Abuse of Lavage.—John Herr Musser believes it unwise to allow patients themselves to do lavage; soon a habit develops in them, which is apt to prove injurious. Every ache or sense of distress, every eructation or heartburn invites the use of the tube. The writer uses it in cases of atonic dilatation, when the retention is extreme; in cases of organic pyloric obstruction; in gastric neurasthenia and certain cases of hysteria, and in some cases of chronic gastritis with subacidity. To ascertain the nature of any gastric lesion or disorder, he makes a practice of analyzing the stomach contents of all patients whose complaints are gastric, and all whose general health suggests imperfect nutrition from defective gastro-intestinal processes. He also employs physical means for determining the size of the stomach—percussion, inflation, etc.—*The Therapeutic Gazette*, November 15, 1900.

Injuries to the Wrist: Diagnosis and Treatment.—Edward A. Tracy gives directions for ascertaining whether the injury be a sprain or a fracture. If the styloids are found in normal relations with the wrist it is a case of sprain. If the radial styloid is on a higher level than its ulnar fellow we have fracture. In the treatment: (1) rest for the joint is important, and may be secured by immobilizing it by means of a piece of wood-plastic splint material, bandaged over the back of the forearm and hand. (2) Massage should be carefully applied to cause absorption of the tissue exudates. This is done by gently grasping and squeezing the forearm a little above the swelling, and then relaxing the hold and repeating the grasp and squeeze about a half-inch below, and continuing to do this until the lower limit of the swollen tissues is reached; then a swift gliding pressure from below upward (toward the elbow) should be made. In this way the lymphatic circulation is stimulated and the broken-up detritus absorbed. (3) Pathological adhesions are prevented by properly applied passive motion. The fingers should be bent daily, and the wrist may be bent

about the fifth day, gradually at first. The splint form above described permits of this easily.—*The Virginia Medical Semi-Monthly*, November 9, 1900.

The Technique of Exploratory Craniotomy.—A. Codivilla describes an instrument designed to remove large pieces of bone from the cranial vault, which is capable of making circular, oval, or other shaped openings. The incision which it makes in the bone is almost linear, the loss of bony substance being very slight. It can be used on thick, hard skulls as well as upon thin and soft ones; it works rapidly and accurately, without danger of injuring the skull contents. The instrument can be taken apart, perfectly cleansed and sterilized, and is easily transported. The only energy necessary in its use proceeds from the hand of the surgeon. It is inexpensive.—*Revue de Chirurgie*, November 10, 1900.

Malaria and General Paralysis.—E. Marandon de Montyel concludes from a number of cases studied that acute malaria can cause progressive general paralysis, or general pseudo-paralysis, in predisposed patients. Chronic malaria may not only do the same, but may even create the paralysis in non-disposed persons, but very exceptionally. Acute malaria may cause early progressive paralysis in the predisposed. Malarial symptoms occurring during the course of general progressive paralysis are frequently complicated by cerebral congestions which aggravate the malady. The paralysis which develops under the influence of acute and chronic malaria is nearly always rapid in its course. While the relation between malaria and general paralysis is undeniable, their simultaneous occurrence is rare. The symptomatology and pathological anatomy of general paralysis of malaria lorigin do not appear to possess any special individual characteristics.—*Revue de Médecine*, November 10, 1900.

The Treatment of Cancer of the Female Breast.—James Bell thus sums up the present status of the subject: (1) Cancer is primarily a local disease, extending (*a*) by infiltration, (*b*) by extension along the lymphatics, and (*c*) by metastasis. Cancerous glands are nearly always found in the axilla in this disease. (2) The only treatment which offers the patient any hope is early and complete removal of the growth, extirpating the whole of the infected structures by incisions through the healthy tissues beyond the remotest extensions of the disease. Local recurrence in the axilla is not uncommon. Early diagnosis of cancer is most important—to be followed by early operation. No breast tumor should be looked upon lightly when there is the remotest possibility of its being cancer or sarcoma. In certain of the more advanced cases an operation which would remove all the axillary structures, including the blood-vessels and the brachial plexus, from the level of the first rib outward, would effect a cure in many cases in which, after any lesser operation, early recurrence, and hopeless, miserable, distressing, and painful invalidism for a short time is all that is left for the patient. If necessary an interscapulo-thoracic amputation should be performed. The performance of the operation up to the extreme limit would probably yield the most beneficial results.—*The Montreal Medical Journal*, November, 1900.

Mental Sanitation.—R. W. Bruce Smith urges that the public be enlightened with regard to the nature of insanity in order that they may recognize that heredity is the most potent factor in its causation. They should also know that, as the development of the morbid disposition is most insidious and seldom recognized until late, the consideration of the personal and family history should receive early attention. Many cases of insanity are justly chargeable to the imposition of burdens beyond the capability of the individual. If the conditions under which many cases of insanity originate were properly understood many attacks of the disease might be avoided. The study of child character and the careful consideration of the variability in the development of mental phenomena during the period of growth in the child are all-important. The family physician should take the steps necessary to secure the adoption of these and all precautionary measures, and must be prepared to advise, caution, and restrain, in exercising his influence in the prevention of mental diseases.—*The Canadian Journal of Medicine and Surgery*, December, 1900.

Widal's Test.—Rufino Fiocca considers that this reaction is the best practical method which clinical microbiology possesses for the diagnosis of typhoid fever. If applied once or more times during the course of the disease the reaction will always be found in cases of true, non-lethal typhoid. In some fatal cases it may be absent. If the dilution of the serum be high enough (1 : 40–1 : 50) this reaction will not be found in other infective diseases. In a certain number of cases it may be used for the early diagnosis of typhoid. The time of its appearance and the curve of the agglutinating-power do not furnish absolutely reliable data for prognosis.—*Il Policlinico*, November 1, 1900.

An Inquiry into the Existence of Autochthonous Malaria in Buffalo and its Environs.—Irving P. Lyon and Alfred B. Wright approached their investigation along two lines: 1. What species of mosquitos are found in and about Buffalo? 2. What evidence of the existence of autochthonous malaria is there furnished by examination of the blood? The answer to the first question may be thus summarized. Of the three hundred and seventy-four specimens of mosquitos collected, every one belonged to the genus Culex, and not a single example of Anopheles, the malaria-bearing variety, was found. As to the examination of the blood, that of twenty-eight cases suspected of malaria was examined, and found negative for malarial organisms. Inquiry of practising physicians, and at all the larger hospitals, elicited the reply that malarial cases were seldom seen. The authors have been unable to discover any evidence that proves the development of malaria in and about Buffalo in recent years.—*Buffalo Medical Journal*, November, 1900.

Carbonic-Acid Gas per Rectum in Pertussis.—C. Legrand Kerr describes the following method of relief to be used in cases when there is a complication, or, more particularly, a drug intolerance. While the results have not been uniformly satisfactory, there has been enough success to warrant a more extended trial. A wide-mouthed bottle, of at least one-pint capacity, has a cork perforated with a glass tube which is adjusted so that the end reaches half-way to the bottom of the bottle. To the external end of the tube is attached flexible rubber tubing three or four feet long, on the free end of which is placed a hard-rubber rectal nozzle. The bottle is filled one-third with water in which has been dissolved ʒ vi. bicarbonate of sodium. To this is added ʒ iv. tartaric-acid crystals. The bottle is kept stationary, and as the tartaric acid dissolves slowly the gas is liberated at the proper rapidity for administration. The rectal tube being inserted, the gas is administered for from five to ten minutes, according to age of child. Two or three treatments daily are sufficient. Ephraim explains the effect as the result of the increased quantity of oxygen which reaches the air vesicles, there to be exchanged for the larger amount of carbonic acid contained in the blood in consequence of absorption from the rectum.—*Pediatrics*, November 15, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

MUNICIPAL HOSPITAL REFORM.

THE Bellevue Hospital scandal is still in the high light of public investigation, the recent brutality of some of her male nurses forming the grim background of the revolting picture. Three of the men who cared for a lunatic are charged with actual murder. The alleged cruelty of nurses in the alcoholic wards, as attested by eye witnesses, matches the sternest facts against the wildest imaginings.

In the face of such disclosures the friends of the old and time-honored institution bow their heads in shame and wonder what new mortification is awaiting due development. All admit, however, that the time has come when the real extent of rottenness in its management should be impartially disclosed.

The commissioner of charities is evidently doing his best to that end, and deserves due encouragement in his work. It is hardly fair, however, in his attempt to explain the varied causes of the trouble impliedly to shift their real responsibility on the medical staff. This is certainly inexplicable on any reasonable ground, and inconsistent with any apparent fact.

To all who are acquainted with the working of the hospital the insinuation of the commissioner that the medical board itself needs investigation is a great surprise. It is well known that while the medical staff is virtually held accountable for all misdoings of nurses, ward attendants, and others indirectly concerned in the care of the sick, it has really no power to enforce its regulations. It can make suggestions, but nothing more. The medical board then should scarcely be blamed for what it could not prevent.

Take the management of the insane ward as an example in point. This part of the hospital had for many years an experienced medical superintendent who resigned last spring, and whose particular office was then abolished. It cannot be denied that the medical staff strenuously advocated the continuance of such a superintendency, but without avail. Instead of honoring the appeal, the commissioner of charity shifted the new duties upon an already overworked house staff. This was doubtless considered wise on his part at the time, but the ultimate results can hardly bear out such an assumption. The virtual acknowledgement of error in this regard is now manifest in his finally acceding to the original wish of the board by recreating the office of medical superintendent of the insane, and holding the incumbent to the strict accountability for proper supervision of his wards. Thus, a great deal depends upon how a thing can be explained.

Although the commissioner may have every desire to do his duty so far as he is able, it is not becoming to his manly spirit to divert proper attention from the real interests at stake by simply "investigating" the responsibilities of all those under him, and thus virtually placing himself beyond the pale of ordinary criticism.

While defending the medical staff against the imputation cast upon it, it is only just to the commissioner to say that he himself, although legally responsible to the public for the proper executive conduct of the hospital, is very much handicapped by outside political influences. When we say he has done the best he could under the circumstances, we offer the strongest argument for changing the entire system of municipal hospital management. Whatever may be said to the contrary, the real fact is that the executive management of Bellevue from beginning to end, from top to bottom, is thoroughly political in character.

It can be seriously doubted that the head of the department can actually have at all times and under all circumstances absolute power to discipline the hosts of employees, whose places are made for them by the various political "bosses." Thus, it may not be an easy thing even to discharge an incompetent superintendent, a brutal nurse, or a drunken ambulance driver, who may be the friend of a ward leader. But these are the humiliations of high office which need only to be named to be pitied. And yet we are soberly informed that the hospital has nothing whatever to do with politics.

It is openly asserted that even the medical board is not above utilizing so-called "pulls," social, political, and cliquish, in controlling college interests and in naming favorite candidates as prospective colleagues. However, thus far such alleged practices have not interfered with the construction of a staff composed of good men, although equally competent men may have been crowded out. In any event, the commissioner holds the balance of power in appointing, and then the political influence of the applicant is very apt to determine the result. Still it is comforting to know that politics has nothing whatever to do with the direct treatment of the sick, as the commissioner frankly declares that he is not competent to judge the skill of the doctors.

But whatever may come of the investigation and whatever promises may be made for the future, a reorganization of the entire system of municipal management of our public hospitals seems inevitable. In the latter direction of reform, the proposed charter amendment, giving the hospitals in charge of an independent board of citizens, offers the best opportunities for their practical, broad-minded, and thoroughly systematic administration.

Dr. John E. Weeks has been appointed professor of ophthalmology at the University and Bellevue Hospital Medical College, to succeed the late Dr. Henry D. Noyes.

THE ETIOLOGY AND TREATMENT OF TABES DORSALIS.

Disease is scarcely a less complex process than life itself, and it should be borne in mind in connection with etiology that, while one cause or set of causes may be more prominent than others, the development of the morbid process will require the conjunction of all of several. Disease has not inaptly been compared to a closed chain, which is incomplete so long as a single link is missing. The links are represented by the causative factors, exciting or predisposing; and it should be the object of the clinician to prevent or to destroy the continuity of the chain. In an interesting communication on the etiology and treatment of tabes dorsalis, Pel (*Berliner klinische Wochenschrift*, 1900, Nos. 29 and 30) expresses the opinion that the principal factor in the etiology of many diseases of the nervous system probably consists in morbid irritation, with resulting impairment of nutrition, of the nervous elements by soluble substances circulating in the blood—in other words, a toxic process. In this connection it should be borne in mind that there are great variations in individual susceptibility, that minimal amounts of toxic substances are capable of exerting an injurious influence, and that each exhibits an elective affinity for different parts of the nervous system.

That the influences under consideration are operative in the etiology of tabes dorsalis is indicated by clinical experience and pathological-anatomical findings, symmetrical degeneration of nerve cells taking place simultaneously or consecutively at widely separated points; as, for instance, the posterior roots, the intervertebral ganglia, the posterior columns, the bulbar nuclei, the peripheral nerves. At the same time, different symptoms of varied localization appear, as, for instance, lancinating pains, ocular disorders, weakness of the bladder, bulbar and ulnar symptoms, and disorders of the sexual functions. For the foregoing reasons, tabes dorsalis is believed to be of hæmatogenous toxic origin, although the identity of the poisonous agent or agents has not yet been established; the deleterious effects being exerted directly upon the cellular elements, but only when the resisting-power of these has been lowered by other injurious influences. All agencies increasing the irritability of the nervous system and lowering its resistance favor the development of morbid processes; as, for instance, excesses of all kinds, exposure to cold, overexertion, traumatism, acute infectious diseases, emotional disturbances, hereditary predisposition. Syphilis, without doubt, plays the most important rôle in the etiology of tabes dorsalis, which is essentially a disease of large cities, and to whose development the strains and competitions of modern life materially contribute. Alcohol and tobacco also are contributing factors.

In the prophylaxis of tabes dorsalis, the most important measure is the avoidance of syphilis, and, in the event of syphilitic infection, the institution of thorough and systematic treatment. In addition, care should be taken to avoid constitutional debility, increased irritability of the nervous system, and lowering of its resisting-power, and, therefore, all of the predisposing influences. When tabes is already developed, the mode of life should be carefully regulated and made simple and quiet, especially excesses of every kind and over-exertion being avoided. A spirit of hope should be sustained, and the patient not oppressed with the incurability of his disease. Mercurials should be employed only when symptoms of syphilis are still present, when tabes has developed a short time after symptoms of syphilis have been present and effective antisyphilitic treatment has not been employed, and when the clinical picture exhibits peculiarities indicating involvement of the spinal or cerebral meninges, and the possibility of the presence of actual syphilis of the cord cannot be excluded. Perforating ulcer of the foot is sometimes favorably influenced by mercurial treatment. Not much is to be expected from the administration of potassium iodide, although some of the symptoms, such as pain, are occasionally mitigated thereby. Strychnine exerts a favorable influence on weakness of the bladder, the gastric functions, etc. The salts of silver may also be employed.

Symptomatic or palliative treatment may require the administration of such drugs as acetanilid, phenacetin, antipyrin, pyramidon, sodium salicylate, cocaine, salophen, quinine, chloral, or applications of ichthyol, or the use of warm baths for the relief of lancinating pains. The application of a flannel bandage, as well as cold or warm affusions and cutaneous stimulation, appears occasionally to exercise a mitigating influence, and a band firmly applied about the abdomen may ameliorate the distressing girdle sense. Relief may sometimes be afforded by suspension or by extension of the spine by stooping forward. Efforts should be made to avert the crises —of which the gastric are the most common—by appropriate hygienic and dietetic measures. Rest in bed, with the avoidance of all irritation, and the employment of anodyne measures and remedies for the control of vomiting, will be indicated. In severe cases morphine will be the only remedy that will afford relief. In mild cases nervines, such as bromides, cocaine, antipyrin, or opium may suffice. They may advantageously be administered by the rectum. If the paroxysms be long continued, nutrient enemata may be required. In the intervals the prostration should be relieved by rest, nutritive diet, and tonics. For the weakness of the bladder strychnine and ergotin may be employed, preferably injected subcutaneously in the vicinity of the viscus. To neutralize the bodily weakness small doses of arsenic may be administered. This metal, in appropriate doses, together with rest and a suitable diet, constitutes an admirable remedy for nervous, emaciated, and debilitated individuals. Baths and other hydrotherapeutic measures, climatic treatment, electricity, massage, supporting apparatus, stimulants, are measures that, if they have no direct influence upon the tabic process, favorably influence certain symptoms, as well as the general condition. Paræsthesiæ may be relieved by the faradic brush, motor weakness by the galvanic and the faradic current, atonic weakness of the back by suitable jackets, and pain by stimulation of the skin.

For the ataxic movements, so called, compensatory exercises may be advantageously practised systematically, for the purpose of both education and exercise.

STERILIZATION OF DRINKING-WATER FOR ARMIES IN THE FIELD.

Typhoid fever in every war has claimed more victims not only than wounds caused by weapons of destruction but even than any other disease. The modern conditions of warfare, though far more sanitary than those of ancient times, do not appear to have exerted any very potent influence in decreasing the death roll from this malady. The report of the commission appointed to inquire into the various causes of death among our soldiers during the Spanish-American war has just been handed in, and from a perusal of this document the fact is gathered that enteric fever was responsible for the great majority of fatalities. The reasons assigned for this peculiar prevalence are many, but all are agreed that to the drinking of polluted water is due a large proportion of the typhoid-fever cases. The South African campaign is another prominent example of the wholesale devastation effected by this disease when it once gains a foothold among a large body of men. It is contended by some that this incidence and mortality are almost exclusively owing to the contamination of the drinking-water. What is needed is an effectual method of purifying the drinking-water. Filtration and boiling are the means which suggest themselves for sterilizing water. *The Medical Magazine*, November, commenting upon the subject, says: "Filtration must be done through the porcelain candle to be effective, but it is too tedious for practical uses in connection with great bodies of troops and for emergencies. Boiling is also inconvenient, and the cooling process entails waiting." The German government has caused a series of investigations to be made with respect to this matter, and some of the results have been given by Dr. MacWeeney (*Journal of State Medicine*, October, 1900). Tea and coffee were useless; brandy and wines were inefficient; formalin gives the water an objectionable taste and may injure digestion; permanganate of potassium was effective, but the drug was with difficulty got rid of afterward; alum, lime, ferric chloride, peroxide of hydrogen, iodine, and chlorine were all tried and found practically unsuitable. Of all the substances to which a trial was given the author accords the preference to bromine. In a former number of the *Journal of State Medicine* the author described Schumburg's method of employing this element in the disinfection and sterilization of drinking-water. It may prove useful to recapitulate the conclusions at which he has arrived: (1) Free bromine added to drinking-water in the proportion of 0.0692 per litre (=4.2 grains per gallon) kills all pathogenic germs, including those of typhoid and cholera, within five minutes. (2) In view of the difficulty of measuring bromine it is used dissolved in KBr solution according to the following prescription: Bromine, 21.91 gm.; potassium bromide, 20 gm.; distilled water, 100 gm. (3) The readiest way to estimate the free bromine in the solution is to add KI and starch paste and titrate the iodine set free with hyposulphite of sodium. (4) When the water is rich in ammonia or organic matter in solution, enough bromine must be added to produce a yellow coloration lasting for about half a minute. Visible impurities and coarse suspended matter must be removed by a rough process of sand filtration. (5) The bromine is to be got rid of when it has been acting for five minutes. For this purpose a nine-per-cent. solution of ammonia was at first suggested, but the object is now accomplished by means of tablets of the following composition: Sodium sulphite, 0.095 gm.; sodium carbonate exsiccated, 0.049 gm.; mannite, q. s., one tablet to be used for a litre of water. In from one to two minutes all taste and smell of bromine have disappeared. Bromine is best conveyed in sealed glass tubes containing enough for 100 litres of water. With the overcoming of the difficulties in the way of purifying water effectively, in camps or on the march, the most important advance toward abolishing typhoid fever among soldiers will have been made. Some of the portable filters now in use are said to answer the purpose fairly well, but at the same time the best of them is far from perfect. Schumburg's method of employing bromine may clear the water of pathogenic germs, but it would seem to be too elaborate and intricate for use with soldiers on the march. If bromine possesses the qualities claimed for it, is it not possible to devise some more simple mode of utilizing them? There is a wide field for investigation here, and certain it is that to the man who discovers the means of purifying water by uncomplicated methods will come both fame and money.

THE ETIOLOGY OF DEGENERATION.

Prevailing currents of thought appear to be healthfully pervaded by sound biological doctrine, and we are coming to have clearer conceptions with regard to the respective influences of heredity and environment. Life is no longer viewed with superstitious awe, but as a manifestation deserving of the most intelligent and liberal study. Much has been written in recent years concerning degeneration, sometimes upon insufficient grounds and at other times without a proper judicial regard for all of the facts; and the significance of the term has been largely lost by reason of its adoption into popular parlance.

As the result of a study of the stigmata of this condition, as observed in soldiers in the course of his duties as an army surgeon, Charles E. Woodruff (*American Journal of Insanity*, vol. lvii., No. 2, p. 203) defines a degenerate as an abnormal individual whose variations or stigmata are developmental and due to an unstable nervous system. Such variations, it is thought, may be dependent also upon disease resulting from instability of the nervous system, such as rachitis and infantile paralysis. Inasmuch as this instability may be of widely varying degree, it is at times difficult to make a distinction between the degenerate

and the normal. Here it is that education and environment enter and help to decide the result.

Unfortunately, degeneration may give rise to anomalies identical with those resulting from involution, or the retrogression of parts once useful, but no longer so. The one process is unwholesome and leads to extinction, and its variations depart widely from the parental form; while the other process is wholesome and favors survival, and its variations do not depart widely from the parental form. Thus, civilization is responsible for the wide diversity in normal variation, and the result has been a minute subdivision of labor, so that an individual may throughout his whole life be engaged in one narrow pursuit, densely ignorant of all subjects outside this specialty.

The body and the brain of a race react to its environment, increasing amid adverse surroundings, and vice versa. Civilization is a product of the intellect, but it can add nothing to brain-growth. In savage life the tendency is toward uniformity, by reason of sameness of pursuit; while in civilized life variation is the rule, for the opposite reason. Such normal variation, which may, however, be identical with that resulting from degeneration, is to be identified by its resemblance to similar variation in the parent, while the reverse is true of unstable or degenerate development.

It has been shown that acquired modifications due to use, disuse, or general environment are not transmissible from parent to offspring; so that nervous instability must be looked upon, not so much as a matter of inheritance, but rather as a result of interference with nutrition, poisoning by toxins or alcohol, or of mechanical accidents to the ovum—an acquired characteristic in the strict scientific sense. There is thus ground for suspicion that degeneration is not hereditary, but that the ova always tend to revert to the normal if permitted so to do; so that if the degenerate were placed under favorable environment there might be hope of regeneration. Unfortunately, however, the opposite conditions commonly prevail, and purification takes place by elimination.

The importance of these modern doctrines resides in their application to the care and raising of the children of degenerates, from which such admirable practical results have already been obtained. Degeneration may possibly be due to vicious causes acting injuriously upon the ovum before or after fertilization, and diverting it during development from the normal groove into which it is naturally directed by the hereditary impulses accumulated by natural selection from millions of previous generations.

If degeneration were hereditary there would be an end to hope of regeneration, but genealogical studies demonstrate the reverse. Aristocratic and degraded families generally become extinct or revert to the average within a few generations unless kept alive by intermarriage with new normal blood. The children of degenerates are degenerate from environmental and not from developmental causes, and the remedy consists in the removal or avoidance of the deleterious influences. The increasing recognition and application of this principle augur well for the future of the race.

A certain degree of nervous instability must be looked upon as a normal variation resulting from the greater development of the nervous system that is an expression of our higher civilization, and the transmissibility of this condition must be admitted. The average man is not degenerate, and the species is carried on and modified by individuals varying least from the average, while those at either extreme die out or tend to return to the normal or average.

News of the Week.

Appendicitis in an Infant.—A child six weeks old died with intestinal symptoms a few days ago in Yonkers, and the autopsy revealed extensive gangrenous appendicitis.

Dr. Charles Warrenne Allen, adjunct professor at the Post-Graduate College, accepted an invitation to give a lecture and hold a clinic on skin and venereal diseases at the Detroit Medical College, last week.

The Spitting-Habit in Brooklyn.—The officers of the Brooklyn Rapid Transit Company have issued a notice which the conductors are to hand to any person whom they see violating the health ordinance against expectorating in the cars of the company. The notice reads as follows:

"The Brooklyn Rapid Transit Company would respectfully call attention to the fact that 'spitting in cars is forbidden by the board of health of this city.' Any violation of this section of the sanitary code shall be treated and punished as a misdemeanor, and the offender shall also be liable to a penalty of $250."

A Lengthened Medical Curriculum in Germany.—The Imperial government has sent to the Bundesrath a bill regulating entrance to the medical profession, prolonging the period of study to five years and enlarging the subjects upon which the examinations are based. The bill provides for one year of practical work before a license can be granted to practise. This bill, which is intended as a remedy for the overproduction of physicians, meets with the approval of the profession. In connection therewith official statistics published this week exhibit the overcrowding of the medical profession in the large cities. Berlin has one physician to every 798 of population, Breslau one to every 775, Halle one to every 735, and Koenigsberg one to every 681.

The New Lying-In Hospital.—The latest annual report of the Society of the Lying-In Hospital contains a description of the new building which will soon be ready for occupancy. The building has a frontage of eighty-three feet in Seventeenth Street, one hundred and sixty-six feet in Eighteenth Street and one hundred and eighty-four feet in Second Avenue. It has eight stories, is about one hundred and fifty feet high, and is a fireproof structure of steel, brick, and stone. The main entrance will be from the avenue, with side entrances opening on the streets. The material of the front walls is buff Indiana limestone and red brick,

and of the rear walls buff brick. The yard and area walls are of glazed brick. The heat for the building will be furnished by three boilers of an aggregate capacity of six hundred horse power. These boilers will also furnish the motive power for the ventilating apparatus, elevators, laundry, kitchen, and for the ice-making, cold storage, and sterilizing plants. The material for the plumbing fixtures is white enamelled earthenware throughout. Two laundry plants are provided, one for the general laundry work, and one is to be known as the septic laundry. In the septic laundry a sterilizer will be placed and all the laundry machinery is to be driven by electricity. The basement will be devoted to the outdoor work; the first story to the executive offices, the second to the nurses' department, the third to the septic department, and the fourth, fifth, and sixth stories to wards for patients, containing about two hundred beds. The seventh story contains the operating-room, laboratory, kitchen, and laundry, while the eighth story is a continuation of the laboratory, with additional amphitheatre seats for the operating-room. The building will be the gift of Mr. J. Pierpont Morgan. This hospital is one of the oldest institutions for the reception and treatment of the sick on Manhattan Island. The society was organized on December 6, 1798, and the first shelter for homeless and destitute women about to be confined was provided in a small building at 2 Cedar Street, which was opened for the reception of patients in July, 1799.

Medical Society of the State of New York.—The ninety-fifth annual meeting of the society, as previously announced, will be held January 29, 30, and 31, 1901, in the City Hall, Albany. The following is the preliminary programme of the meeting: Tuesday, President's inaugural address, reports of officers and committees, executive business; "Recent Progress in the Treatment of Pneumonia," by James King Crook, New York; "Congenital Dislocation of the Shoulder with Report of Cases," by Daniel W. Marston, New York; "Appendicitis and Menstrual Irregularities," by A. L. Beahan, Canandaigua; "Small Hospitals and their Administration," by Louis Nott Lanehart, Hempstead; a paper, title not given, by Abraham Jacobi, New York; "The Necessity of Greater Conservatism in the Use of Vasodilators, in Certain Cases of Cardiovascular Disease," by Louis Faugères Bishop, New York; "Hernia of the Urinary Bladder," by William S. Cheesman, Auburn; "Treatment of Prostatic Hypertrophy," by Ramon Guitéras, New York; "The Medical Society of the State of New York: its Past and Future," by Albert Vander Veer, Albany; "What is Rodent Ulcer?" by John A. Fordyce, New York. Section in surgery: "Noma of the Genitalia," by Andrew McFarlane, Albany; "Esophoria or Latent Squint," by Francis Valk, New York; "Changes in the Crystalline Lens during Accommodation," by Lucien Howe, Buffalo; "Tuberculosis of the Iris," by W. F. Mittendorf, New York; "Can Interstitial Keratitis be Prevented in the Offspring of Syphilitic Parents?" by Peter A. Callan, New York; "Treatment of Chronic Purulent Otitis Media," by James F. McKernon, New York; "Operations for Deformities Following Pott's Fracture," by W. O. Plimpton, New York; "Indications for Operations upon the Mastoid," by Wendell C. Phillips, New York; "Indications and Limitations of the Vaginal Route of Attack in Pelvic Diseases in Women," by J. Riddle Goffe, New York; "What Complications of Pregnancy, Labor, or Puerperium Justify Abdominal Section?" by William Warren Potter, Buffalo; "The Treatment of Persistent Suprapubic Fistula Resulting after Ovariotomy," by Willy Meyer, New York; "Results Following the Cure of Chronic Defects on the Vesical Function," by Eugene Fuller, New York; "Ectopic Pregnancy, Primary Rupture, the Opportune Time for Making Diagnosis," by George McNaughton, Brooklyn; "An *x*-Ray Study of the Causes of Disability Following Fractures Involving the Elbow-Joint," by Samuel Lloyd, New York; "Contributions to Abdominal Surgery," by James E. Kelly, New York; "Loose Cartilage in the Knee-Joint," by P. R. Furbeck, Gloversville; "Pus in the Peritoneal Cavity," by Robert T. Morris, New York; "The Indications and Limitations of Spinal Cocoainization in Surgery," by George R. Fowler, Brooklyn; "The Results of Nephropexy for Movable Kidney," by George M. Edebohls, New York. Section in medicine: "Relations between Certain Diseases of the Skin and the Menstrual Function," by L. Duncan Bulkley, New York; "Hysterical Anæsthesia and Analgesia," by B. C. Loveland, Syracuse; "Deep Breathing as a Curative and Preventive Measure," by John H. Pryor, Buffalo; "Belladonna vs. Scopolia," by Reynold W. Wilcox, New York; "Disinfection within and without the Body in Diphtheria;" by M. A. Veeder, Lyons; "Diphtheria, After-Thoughts on," by I. N. Love, New York; "Fatty Degeneration of the Heart," by Thomas E. Satterthwaite, New York; "Recent Experiences with Erythromelalgia," by Henry L. Elsner, Syracuse; "A Simple and Accurate Method of Substitute Infant Feeding," by Henry Dwight Chapin, New York; "Leprosy in the Hawaiian Islands," by Charles E. Davis, Albany; "The Tonometer and its Value in Determining Arterial Tension," by Henry L. K. Shaw, Albany; "Pleuro-Pericardial and Diaphragmatic Adhesions," illustrated by colored wax models, by D. H. Goodwillie, New York; "Differential Diagnosis in Diseases of the Spinal Cord," by E. D. Fisher, New York; a paper, title not given, by Carlos F. MacDonald, Pleasantville; "Masturbational Neuroses," by William C. Krauss, Buffalo; "Arthritis Deformans," by Herman Mynter, Buffalo; "Tenosynovitis Calcarea," by Carl Beck, New York; "The Treatment of Puerperal Fever," by Herman J. Boldt, New York; "The Immunizing Effect of 'Rag Weed' in Hay Fever," by H. Holbrook Curtis, New York. Wednesday, Demonstration clinic, conducted by Drs. Albert Vander Veer, Samuel B. Ward, and Willis G. MacDonald of the Albany Hospital staff, at the Albany Hospital; "Contribution to Pelvic Infection in Women," by Charles A. L. Reed, Cincinnati (discussion by J. F. W. Ross, Toronto, Ont.; L. S. McMurtry, Louisville, Ky.; W. E. B. Davis, Birmingham, Ala.; Bache McE. Emmet, New York; William M. Polk, New York; George M.

Edebohls, New York; James Clifton Edgar, New York; James P. Boyd, Albany); "Report of Five Cases of Ovarian Tumors with Twisted Pedicles," by George B. Johnston, Richmond, Va.; President's address, 12:15 on hernia; "Surgery of the Spleen," by J. Collins Warren, Boston, Mass. (discussed by Albert Vander Veer, Albany; Charles McBurney, New York; Robert F. Weir, New York; Robert T. Morris, New York; Thomas Roddick, Montreal, Canada); "The Pathology and Diagnosis of Intestinal Obstruction," by J. B. Murphy, Chicago, Ill.; "Inguinal Hernia," by Merville Ricketts, Cincinnati, Ohio; "Gastro-jejunostomy in Gastrectasis," by A. H. Cordier, Kansas City, Mo.; "Toxin of the Colon Bacillus," by Victor C. Vaughn, Ann Arbor, Mich. Thursday, "Tetanus Following Clean Operation: Report of Cases," by Joseph W. Bissell, New York; "The Advances in State Medicine," by M. J. Lewi, New York; "Aseptic and Antiseptic Precautions in Dental Surgery," by J. B. Ransom, Dannemora; "The Treatment of Delirium Tremens by the Intravenous Infusion of Saline Solution," by James P. Warbasse, Brooklyn; "Report of Case of Brain Tumor; Operation; Improvement," by William M. Leszynsky, New York, and James H. Glass, Utica. The officers for this meeting are: *President*, A. M. Phelps, New York; *Vice-President*, George Seymour, Utica; *Secretary*, Frederic C. Curtis, Albany; *Treasurer*, O. D. Ball, Albany.

The San José Medical College in Manila.—It is reported from Manila that the first question dealt with by the Taft commission affecting the church and the United States government is whether the control of the San José Medical College is vested in the government or in the church. The college was established by bequest in the seventeenth century, and the Jesuit order was given the control of it. When the authority of the Jesuits in the Philippines ceased, the Spanish government assumed direction of the college, and later permitted the Dominican order to conduct San José College as part of the University of Santo Tomás. Following the American occupation, it was claimed that the college under the treaty of Paris came into the control of the United States, and ought not to be controlled by the church. The church authorities insisted that the church had full legal possession. General Otis finally closed the institution, pending a legal decision in the case.

The Plague in San Francisco.—The Texas health authorities persist in asserting that the plague exists and is still spreading in San Francisco. In a report to the governor made on December 20th, the Texas State health officer says that twenty-two cases are known to have occurred in that city since March 6, 1900. He quotes Dr. Kinyoun of the Marine-Hospital service in San Francisco as reporting officially: "I would state that it is my belief that the area of infection is gradually growing wider, so that now there are only three blocks of the Chinese quarter proper in which there has not occurred since March last a case of plague. The conditions which will obtain in the next six months will be, in my opinion, conducive to a further spread of the disease. I believe other cases occurring in San Francisco are being reported under another name."

Philadelphia County Medical Society.—At a stated meeting held December 26th, Dr. Francis T. Stewart read a paper entitled "Profound Shock Following Crush of an Arm; Dermoid of the Ovary; Enormous Ventral Hernia." Dr. Levi J. Hammond read a paper entitled "The Rational Treatment of Chronic Suppuration Within the Antrum and Attic." Dr. J. P. Crozier Griffith read a paper entitled "Scurvy, not Rheumatism, with a Report of Sixteen Cases of Infantile Scurvy." Dr. Griffith laid particular stress upon the fact that pain in an infant not explicable by other cause should always arouse suspicion of scurvy, which would be confirmed by disappearance of the symptoms upon treatment with orange juice and beef juice. Bruise spots, petechiæ, and spongy, bleeding gums are at times also present. Dr. Boardman Reed read a paper entitled "The Treatment of Dilatation of the Stomach."

Warring against Mosquitos in Cuba.—According to a despatch from Washington, Governor-General Wood has issued an order in Havana which declares that the chief surgeon of the department of Cuba has reported that it is now well established that malaria, yellow fever, and filarial infection are transmitted by the bites of mosquitos. The troops are enjoined to observe carefully two precautions: first, they are to use mosquito bars in all barracks, hospitals, and on field service whenever practicable; second, they are to destroy the larvæ by the use of petroleum on the waters where they breed. Pools or puddles are to be filled up. To other collections of water is to be applied one ounce of kerosene to each fifteen square feet of surface twice a month.

A National Psycho-Physical Laboratory.—An endeavor is to be made at this session of Congress to secure the passage of a bill for the establishment of a laboratory at Washington under federal control, for the application of physiological psychology to sociological and abnormal or pathological data, especially as found in institutions for the criminal pauper and defective classes and in hospitals, and also as may be observed in schools and other educational institutions. The plan is not to have a necessarily complete laboratory. It is not to be in competition with other psycho-physical laboratories in our country. Besides these data, it is desired to gather more special data with laboratory instruments of precision and to make such experiments or measurements as are generally considered of value not only by psycho-physicists and anthropologists but by physiological and pathological specialists.

Formal Opening of the Cornell Medical College Building.—The exercises formally opening the new Cornell University Medical College building, which has been in use for several months, were held in the main lecture hall of the building, last Saturday afternoon. Speeches were made by Governor Roosevelt, President Seth Low of Columbia University, Dr.

Lewis A. Stimson, professor of surgery in the Cornell Medical College, and President Schurman of the University.

Smallpox continues in New York, but the cases are few in number and the type of disease is very mild. Vaccination has been more generally practised than in any previous "scare," the number of persons vaccinated during the past six months in this city being estimated at over one million. The vaccinations have "taken" in an unusually large proportion of cases.

Pathological Society of Philadelphia.—At a stated meeting held December 27th, Dr. Joseph Sailer exhibited two specimens of "Malignant Disease of the Intestine." In one the lesion was situated in the duodenum just beyond the papilla of the choledoch and pancreatic ducts, and in the other several feet farther on in the small intestine. Dr. David Riesman exhibited a specimen of "adherent pericardium." Dr. D. J. McCarthy read a paper entitled "Pseudo-Cerebral Porosis in Rabies." Dr. William G. Spiller presented a communication entitled "Remarks upon the Importance of the So-Called Specific Lesions of Rabies." Dr. M. Howard Fussell exhibited a specimen of "Aneurism of the Abdominal Aorta with Fresh Endocarditis."

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy for the week ending December 29, 1900. December 21st.—Assistant Surgeon R. E. Ledbetter detached from the *Monongahela* and ordered to the *Constellation*. Assistant Surgeon C. R. Burr, order of December 19th revoked; ordered to resume duties on the *Monongahela*. December 24th.—Medical Director G. P. Bradley commissioned medical director from May 31, 1900. Medical Director P. Fitszimons commissioned medical director from November 19, 1900. Medical Inspector W. H. Jones, retired, died at Bethlehem, Pa., December 13, 1900. Assistant Surgeon S. S. Rodman and J. M. Brister appointed from December 14, 1900. Surgeon G. H. Barber commissioned surgeon from June 7, 1900.

Obituary Notes.—Dr. Robert V. K. Montfort, of Newburg, N. Y., died on December 29th. He was born in Fishkill village in 1835, and was graduated from the Albany Medical College in 1859. In September, 1862, he entered the federal army as assistant surgeon in the One Hundred and Twenty-fourth New York Volunteer Infantry (Orange Blossoms). He was on every battlefield of the Army of the Potomac from Chancellorsville to the end of the war, and was one of the five original officers who served with the regiment during the whole term of service. He was promoted surgeon in March, 1865, and was mustered out in June of that year. Dr. Montfort was formerly health officer of Newburg. He was a prominent educator and was for many years clerk of the board of education and superintendent of the public schools of Newburg.

Dr. Theodore Giddings died of apoplexy at his home in Housatonic, Mass., on December 28th. He was born in Housatonic in 1837 and was graduated from the College of Physicians and Surgeons in this city in 1868. He served in the Massachusetts legislature in 1886 and 1888.

Dr. Oren George Hunt, a well-known homœopathic physician of this city, died on Christmas eve of hæmatemesis, at the age of forty-two years. He was a graduate of the New York Homœopathic Medical College in 1886.

Dr. Ulysses Higgins Brown, of Syracuse, N. Y., died suddenly in this city on December 27th at the age of forty-nine years. He was a licentiate of the Onondaga County Medical Society in 1878, and was an ophthalmologist of repute. He was a member of both the State medical societies and of several local societies.

Dr. Erastus Edgerton Marcy, formerly one of the most prominent homœopathic physicians in this city, died on December 27th. He was born in Greenwich, Mass., and was graduated from the Jefferson Medical College, Philadelphia, in 1837. He practised as a regular physician in Hartford, Conn., for ten years, and then took up homœopathy, to which he had become a convert. Soon he came to New York, where he acquired an extensive practice and was ranked among the most prominent of his school in the country.

Progress of Medical Science.

Medical News, December 29, 1900.

A Theory of the Physiology of Spinal Anæsthesia.—H. H. Stoner states that the term "medullary narcosis" is misleading, since it gives the impression that the injection is made into the substance of the cord, whereas in reality the solution is thrown into the subarachnoidean cavity some distance below the termination of the spinal cord. The most plausible theory as to the way in which the poison gains access to the cell-bodies is that the axons, occupying the cavity into which the solution is thrown, absorb it and transfer it by way of their vascular supply back to the cell. It is noteworthy that the neurons most profoundly affected by the solution are those that go to make up the cauda equina. The motor neurons, the axons of which pass through the cauda equina, apparently go on performing their function of transmitting motor impulses unmindful of the presence of the toxic agent. It must not be supposed that these neurons are unaffected by the solution. The cytological structure of their cells undergoes the same morbid change as do those of the sensory neurons, but owing to the direction of the motor current and the relation of the end plates of the peripheral motor neurons to the muscle fibres, their capacity for transmitting motor stimuli to their destination in the muscle is not seriously handicapped. Stimuli over the sensory tract are prevented from reaching their destination owing to paralysis and withdrawal of the arborizing extremity of the peripheral sensory neuron from contact with its associated one, but in the case of the peripheral motor neuron no such effect takes place. The solution paralyzes the arborizing processes of this collateral branch as well as those of the ascending branch, and such being the case it is withdrawn from functional relation to the peripheral motor neuron and reflex activities are thereby inhibited.

The Nitrite Treatment in Syphilis.—William Browning states that the nitrites are indicated in all syphilitic diseases of the arteries, as a rule in all specific affections attended by pain, in all syphilitic brain troubles, and especially in the later and hereditary forms of syphilitic disorder (cerebral, spinal, peripheral). This lumps clinical indications rather than differentiates them, but for present and practical purposes it may suffice. With these indications goes the mandate immediately to employ such other and more directly specific agents as the case demands. The writer finds the hypodermic use quite unsuitable. As nearly a continuous action as possible is desirable, hence administration by mouth answers best. The various preparations have their special indications. All of these agents

are highly explosive if improperly handled. The sodium salt should be given in solution, while the sugar preparation is available in tablet form.

The Value of the Schumburg Method of Purification of Water for Military Purposes.—John H. Huddleston reviews Schumburg's experiments, from which he concluded that bromine is the only chemical disinfectant of the many he tried which yielded successful results. He reported that .06 gm. of bromine kills the pathogenic bacteria in one litre of water in five minutes, and that then the bromine can be neutralized by ammonia so that a clear, tasteless, and odorless water results. After more elaborate experiments Schumburg found that the bromine is best handled in a potassium-bromide solution: ℞ Potassii bromidi, 20.00; bromi, 21.91; aquæ q.s. ad 100.00; for the bromine and for the neutralization tablets each containing sodii sulphitis, .095; sodii carb. exsic., .040; mannit. q.s. Of the solution $\frac{1}{5}$ c.c. is sufficient for one litre and is neutralized by one tablet. The method described is rapid and the solutions are easily made and not expensive.

The Failure of the Consensus Judgment with Reference to Tuberculosis.—By Charles Denison.

Boston Medical and Surgical Journal, Dec. 27, 1900.

Operative Treatment of Goitre.—J. Collins Warren says that the operative treatment of tumors of the thyroid gland appears to be indicated in rapidly growing tumors in young persons in whom the medical treatment has been ineffective. As soon as the tumor has reached a size sufficient to cause pressure symptoms, the operation becomes urgent. The operation consists either in the removal of a limited portion of the gland, such as an isolated lobe or a more or less independently growing adenomatous mass of solid gland tissue, or in the enucleation of a cyst. The author describes the steps of the operation in detail. He has operated upon only two cases of exophthalmic goitre, and his experience has not been encouraging. In benign goitre he has had but one death. He has seen a number of cases in which treatment by thyroid extract has produced no effect. He is not cognizant of a single case in which it has effected a permanent cure.

Journal of the American Medical Ass'n, Dec. 29, 1900.

Hemorrhagic Infection in an Infant due to the Typhoid Bacillus.—George Blumer reports this case as probably belonging in the category of congenital typhoid infection. The mother, although in apparently perfect health at the time of the child's birth, gave the history of an acute illness four and a half months previous that indicated typhoid fever. The child, which died on the ninth day, had vaginal hemorrhages, bleeding from the gums, and a petechial eruption over the forehead. The post-mortem anatomical diagnosis was as follows: Hemorrhagic follicular colitis and ileitis. Swelling of the spleen. Swelling of the mesenteric lymph glands with hemorrhage. Cloudy swelling of the liver and kidneys. Congestion of the lower lobes of the lungs. Dilatation of the uterus with hemorrhage into the endometrium. Hemorrhages into the kidney and the submucosa of the bladder. If this is really an example of congenital typhoid fever, then it must be assumed either that the typhoid bacillus was present in the mother's circulation for four and a half months after the attack, and gained entrance to the blood of the child only shortly before birth, or that it was transmitted to the child at the time of the mother's attack, and remained latent in its tissues until just before birth. The latter probability would seem more likely on account of the fact that the typhoid bacillus is seldom found in the blood of adults in any number, even during the attack, and it would, therefore, seem extremely unlikely that it is ever present four and a half months later. It would seem likely, then, that the case was one of congenital typhoid fever in which the bacilli had remained latent in the fœtal tissues for a period of four and a half months. The septicæmic character of the disease is characteristic of this class of cases, and the hemorrhagic tendency is seen at times both in children and adults.

Local Use of Guaiacol in the Treatment of Frequent, Painful Urination.—Jesse Hawes believes that guaiacol is applicable only to those cases in which the cause of the symptom is located in the extreme inner portion of the urethra, usually in a space three-quarters to one and one-quarter inches external to the urethro-vesical orifice. Many diseases of the genito-urinary system cause urgent micturition, yet it is probable that all other causes combined furnish fewer cases of frequent painful urination than the one condition under consideration. Guaiacol in a fluid condition should not be permitted to cover the mucous membrane; barely enough to make a surface application is all that is desirable; thus applied, it is an anæsthetic and mild stimulant. It gives rise to much less pain than the usual local applications. A few applications from five to ten days apart, in the writer's experience, have been more satisfactory to patient and physician than any remedy previously used. It has cured twenty per cent. of his patients. About seventy per cent. are improved markedly. The application will not cure frequent and painful urination due to an enlarged prostate, but in so far as a congested prostatic urethra accompanying prostatitis is a factor in enuresis, the application of this agent is indicated. There are other diseases that cause enuresis, however, which will not be improved by this treatment.

Philadelphia Medical Journal, December 29, 1900.

Some Anomalous Cases of Typhoid Fever.—Augustus A. Eshner reports several cases of typhoid fever in which the symptoms were far from typical. One was a case of unusual severity, the fever lasting irregularly for three months; another was unusually mild, and the nature of the case would probably not have been recognized had not the man been brought to hospital for treatment of a fracture of the leg. Two cases were marked by hemorrhages and petechial eruptions. A fifth case was one which was believed to be typhoid fever without intestinal lesions, but this supposition could not be verified or disproved, although the patient died, as permission to make an autopsy could not be obtained. The author reports the cases as a warning to the clinician to be ever on the alert lest he overlook mild or atypical cases of typhoid fever, or mistake for typhoid fever other diseases which may simulate it more or less.

A Clinical Lecture on Syphilitic Diseases of the Tongue.—Christopher Heath states that primary syphilitic disease of the tongue is very rare. An important point to remember is that a chancre of the tongue, like a chancre of the lip or of the finger, does not present that remarkable hardness which a chancre on the genital organs does. There is no doubt that mucous tubercles in the mouth can produce a primary chancre in the mouth of another person. One symptom of constitutional syphilis about the tongue and mouth is the development of inflammation superficial in its character. With it there is generally a shedding of the superficial layers of the mucous membrane of the tongue. Inflammation may go on to ulceration, which is generally multiple. There may be also a chronic thickening of the tongue. The treatment for all kinds of secondary syphilis of the tongue is mercury. This drug must be pushed not merely constitutionally but locally. A mouth wash of a strength of gr. ¼ of perchloride of mercury to the ounce is excellent—this strength may be gradually increased. The lotion should be held in the mouth for five minutes two or three times a day. For the internal method of administering mercury, the writer prefers the inunction method. As to tertiary syphilis, Jonathan Hutchinson's words may be quoted: "If you irritate a part sufficiently long, you may grow epithelioma." The treatment of a gummatous condition consists of full doses of potassium iodide plus a mercurial mouth wash. Many cases ot leukoplakia arise in conjunction with syphilis. Syphilitic warts at the back of the tongue should not be confused with the condition that is sometimes seen on a perfectly healthy tongue. When the enlargement is merely an hypertrophied papilla, it should be touched with the acid nitrate of mercury.

Remarks on Chronic Enlargement of the Pancreas in Association with or Producing Attacks Simulating Biliary Colic.—Gilbert Barling declares that diseases of the pancreas are not yet as well understood, or as thoroughly worked out, as diseases of the other abdominal viscera. The writer then reports four cases of enlargement of the pancreas found accidentally in operating on the gall bladder or ducts. In two, gall stones were not found. The common features in these cases are enlargement of the head of the pancreas with attacks of colic and more or less complete blocking of the common bile duct. The four patients undoubtedly suffered from chronic pancreatitis, which in two of them led to an ill-founded diagnosis of gall stones. In the other two gall stones coexisted, and possibly, by inflicting damage upon the common duct in their passage, directly induced the pancreatic inflammation. The possibility that, in the occurrence of thickening about the head of the pancreas with jaundice, a malignant growth is not present, is held out by such cases as those described in this article.

Otomycosis in the Tropics.—H. Campbell Highet believes otomycosis, or the growth of fungus in the external auditory meatus, to be rare in temperate climates. All the cases of the writer were in adult Europeans. Children are said to be exempt. The symptoms vary. There may be itching, pain, and discharge. In typical first attacks, the meatus is seen to be filled up with a soft wool-like substance. The disease is readily curable if carefully attended to. As much of the fungus as possible should be removed by a probe and the canals cleansed with warm bichloride of mercury solution. After the fungus has ceased to grow a powder is insufflated consisting of boric acid, bismuth salicylate, and oxide of zinc. The ear should be kept clean and dry as a prophylactic measure.

Some Points in the Treatment of Spinal Abscesses.—A. H. Tubby emphasizes the following points: (1) Do not wait to open a spinal abscess until the skin is reddened and involved. (2) So far as possible open the abscess at certain "seats of election," the places of evacuation to be decided by the direction taken by the abscess and by the surgeon. (3) Wherever evacuation is decided upon, let it be done as far as possible away from the groin, and in such a position that more than one opening can be made into the abscess cavity. (4) Carefully cleanse the cavity and rub the interior thoroughly with menthol or iodoform solution. (5) Avoid drains of all kinds. (6) Be careful to carry out perfect aseptic measures from first to last.

Intraperitoneal Rupture of the Bladder.—W. Percy Blumer reports the case of a man aged thirty-five years, who fell, striking his abdomen. Four days after the injury the patient walked over two miles to the infirmary, where he was operated on. One hundred and ninety-six ounces of urine were drawn out by the catheter. There were no symptoms of peritonitis, and in three months the patient was perfectly well.

Mechanical Constriction of the Uvula.—W. E. Hadden reports this interesting case in which the uvula became accidentally constricted by a bit of thread, causing distressing symptoms of vomiting and retching. The patient was a linen weaver, and relief was afforded by snipping off the swollen part with scissors.

The Use of Tuberculin in the Treatment of Lupus Vulgaris.—Edward F. Maynard reports the successful treatment of a tuberculous nose by tuberculin. Reaction followed the injections. The patient is still well, although a year and a half have passed since her admission to the hospital.

A Case of Acquired Partial Exstrophy of the Bladder Consecutive to a Double Hypogastric Cystotomy; Operation; Cure.—Louis Tixier and Charles Viannay state that although by exstrophy of the bladder a congenital malformation is generally indicated, still this case by analogy seems entitled to the term "acquired exstrophy of the bladder." The two operations on the bladder were performed for the removal of vesical calculi. The first operation was performed in 1856, and forty years later another calculus developed after an attack of nephritic colic. Cystitis also developed, followed by suppurative pericystitis. After the second operation under these unfavorable conditions, a large vesical opening was left through which the upper pole of the bladder pushed, forming a permanent tumor and a true acquired partial exstrophy of the bladder. This complication of hypogastric cystotomy is quite rare and seems worthy of report. This patient was operated on for his trouble, and as the result was only partially favorable, a urinary fistula persists. Still the condition is greatly improved.—*Gazette Hebdomadaire*, December 2, 1900.

How to Treat Infantile Paralysis.—H. Gillet speaks of electricity, hydrotherapy, massage, and drugs. By the electric current, faradic or galvanic, the extent of degeneration caused by the disease may be discovered. Massage and gymnastics combined form a complement to electricity. Various douches and baths, *e.g.*, sulphur bath, salt bath, sea bath, etc., are effectively associated with the electrical treatment. When there is impossibility of active movement, massage finds play. Friction applied more especially to the injured member with simple or aromatic vinegar or with cologne, etc., is grateful. The preparations of ergotin used occasionally from the beginning of the febrile period and strychnine for the later period are valuable. Orthopædic apparatus is sometimes indicated. The treatment of this disease must be pursued with perseverance and care.—*Journal des Praticiens*, November 22, 1900.

Prophylaxis of Tuberculosis.—D'Hotman calls attention to the danger of transmitting the tubercle bacillus through expectoration. The dejections are likewise a source of propagation of the deadly bacillus. The writer believes that water is also an agent for transmitting the bacillus. He does not believe that density of population plays an important rôle. As to dwelling-houses and buildings of various sorts, they form a hearthstone of propagation. As to the disposal of the sources of infection, the writer thinks that this subject is treated theoretically to a great extent, but that the practical side is much neglected. Much is to be accomplished in this direction in the future.—*Journal de Médecine de Paris*, December 2, 1900.

Medical Examination of Children; the Normal Infant.—G. Carrière mentions several conditions necessary to the successful examination of children. Great gentleness must be exercised; the voice should not be raised, but must convey authority and firmness. Patience must be observed by the physician even in the most trying moments, for it eventually brings success. Children should be amused and distracted when auscultation is necessary. A regular routine must be observed. The attitudes should be closely observed both in sleep and in the waking hours. The writer then goes into the minute details of the examination of the different parts of the body.—*Le Nord Médical*, December 1, 1900.

Münchener medicinische Wochenschrift, Dec. 4, 1900.

The Intestinal Action of Atropine.—Paul Ostermaier, inspired by the good results obtained by Batsch and others in the treatment of intestinal obstruction with this drug, used it with success in various conditions of reflex enterospasm or secondary paresis of the intestine with or without spasm. The causes of the trouble were hepatic or renal colic, cardialgia, epididymitis, lumbago, movable kidney, traumatism, etc., and in most instances laxatives had already been tried without avail or even to the patient's detriment. In all cases the effect of the atropine was to relieve promptly the subjective symptoms, pain, nausea, and distention, and to cause a copious fecal evacuation in from twelve to thirty-six hours. In the few instances in which the desired result was not promptly obtained a very mild laxative, such as a teaspoonful of castor oil, was sufficient to produce an easy stool. The drug was given either subcutaneously or in pill form in doses of ½ mg. night and morning. In conclusion, the author suggests the trial of this treatment in the severe intestinal paresis so often following laparotomies.

The Causative Treatment of Tuberculosis.—Edwin Klebs advocates the use of tuberculocidin and antiphthisin, two preparations known as TC and AP respectively, but details as to whose method of manufacture are not given. A number of cases are reported with very favorable results,

and experiments on animals seem to show that the new agents actually have the power to neutralize the toxins of the disease even when these have been artificially introduced into the organism by injection. The author emphasizes the fact that it is not fair to expect from this nor from any other method of bacteriotherapeutics any effect on lesions not directly produced by the specific organism in question, and also that it is of great importance to remove, as nearly as may be, any existing complication before the treatment is begun. An interesting observation is that the tuberculocidin is active when given by the stomach, and indeed produces less febrile disturbance when so administered than when subcutaneously injected.

The Significance of Alcohol in Hand Disinfection.—Egbert Braatz supplements a former article on this topic, in which he called attention to the fact that the value of alcohol in the various disinfecting procedures in use could not be due solely to its fat-dissolving or intrinsic bactericidal power, by a reference to the chemical law which makes the solubility of air in alcohol ten times greater than in water. Inasmuch as the skin is full of minute interstices holding small portions of air, the action of any fluid antiseptic must be greatly impeded, and if its use be preceded by the application of alcohol, which almost instantaneously removes this obstacle, the resulting cleansing will be much more thorough.

Amyloform in Chronic Middle-Ear Disease.—H. Sagebiel's conclusions are that amyloform is not adapted for use in the treatment of suppurations of the middle ear, since its power of checking the pus formation is far inferior to that of other agents in use, and it also is too irritating to the tympanic cavity. A third disadvantage is its tendency to form concretions of varying degrees of hardness, whereby secretions are dammed back and the already existing trouble is aggravated.

A Method for the Determination of the Internal Friction of the Blood in Man during Life.—By Carl Hirsch and Carl Beck.

Berliner klin. Wochenschrift, Nov. 26, and Dec. 3, 1900.

The Treatment of Infection Arising in the Uterus.—Abel calls attention to the large number of cases of infection from the uterus, a number still large in spite of modern antiseptic methods. He describes the various clinical aspects of the subject, and then passes to the consideration of treatment. He is sceptical as to the value of antistreptococcus serum. The same attitude is held toward the method of artificial abscess when an abscess is purposely induced by the injection of sterile oil of turpentine, the injection being made in the calf, the theory being that the abscess contents are sterile and that there is generated an antitoxin which counteracts the deleterious influences spreading from the uterine site. Two procedures which in his hands have yielded good results are saline transfusions and oxygen inhalations, these being used, of course, in addition to the local antiseptic measures. If pyosalpinx or ovarian abscesses result from infection laparatomy is advised.

Diffuse Chronic Œdema of the Skin with Involvement of the Larynx.—W. Lublinski's patient was a woman aged fifty-two years, with general cutaneous œdema which had begun in the eyelids three months previously. The lymph glands were not involved, the thyroid was normal, fever absent, and the pulse but little accelerated. In the larynx œdema involved the aryepiglottic folds, arytenoid cartilages, and interarytenoid commissure, but there was no redness. Physical examination otherwise was negative. The urine was normal throughout. She improved slightly on arsenic, somewhat on lukewarm baths with cold rubbings, and greatly (though not entirely cured) on thyroid extract. Lublinski does not believe that the complex of symptoms pointed to a myxœdema, as the thyroid was not enlarged and she did not present many of the common features of that affection.

Ziehen's Modification of Flechsig's Opium-Bromide Cure for Epilepsy.—E. Meyer and C. Wickle give their experience with this plan of treatment, which consists essentially in the administration of gradually increasing doses of opium, together with a careful attention to the diet and the application of hydrotherapy. The point especially insisted on is the size of the initial doses of bromide and their long continuance. Clinical histories are given in detail. The authors find that this method lessens the number of attacks and contributes to both physical and mental well-being.

Deutsche medicinische Wochenschrift, Dec. 6, 1900.

A Résumé of the Conclusions Reached by the Malaria Expedition.—R. Koch believes that the various subspecies of the malarial parasite which many authors have brought forward of late are not truly distinct varieties and in his studies of the malarial fevers in various parts of the world he has found only the three classical types. These are the tertian, the quartan, and the crescent forms, for which latter the names of æstivo-autumnal and malignant tertian have also been proposed, but which the author thinks is most suitably known as the "tropical-fever organism." The work of the expedition was done in New Guinea, a field particularly adapted for such investigation, for owing to the perpetual petty warfare carried on by each village with the neighboring ones each community exists under absolutely ideal quarantine conditions, while quinine or other medication is wholly unknown. The finding of the disease in every one of the villages visited, therefore, proves that it is endemic for those particular localities, while the primeval conditions under which the patients subsist make it sure that the course of the malady has been entirely unchanged by treatment. It is of extreme interest to note that from eighty to one hundred per cent. of the children under two years of age were found to be malarious, while in no instance were the parasites found in the blood of individuals over ten years old, which fact the author construes as indicating an acquired immunity to the disease, which can be attained only under such conditions as obtain in these cases in which the disease is allowed to run its full course absolutely unchecked. Splenic tumor was very noticeable in all the smaller children, but no enlargement could be detected in any of the adults examined, nor was there evidence of any immediate or late sequelæ to the disease.

Processes of Repair in Damaged Tissues.—Ernst Ziegler in the first part of his contribution lays down the thesis that injury to the tissues of man or the higher vertebrates of a nature to cause solution of continuity is speedily followed by reparative efforts which are inaugurated by a formation of new cells. As long as the lesion is of small extent and only isolated cells or groups of cells perish—for example, those of the entoderm or ectoderm—the restitution of these elements is possible and perfect repair results. If the damage is more far-reaching, however, and there is in addition to the epithelial defect some interruption of continuity in the vascular and connective-tissue systems, the process terminates less favorably, since the gap is filled with an inferior type of tissue, viz., cicatricial tissue. If the injury was very extensive, a permanent defect results, for the cicatricial tissue does not fully replace the lost portions and restoration of serious tissue loss never occurs. The remainder of the paper is devoted to a seriatim enumeration of the various tissues with the mechanism of repair that follows injury to each and is not adapted for reproduction in brief.

Attacks of Apnœa in Diphtheritic Paralysis.—Wilhelm Ebstein reports the case of a ten-year-old girl who came under observation suffering from pharyngeal, lingual, and recurrent palsy with impaired accommodation and weakness of the extremities following diphtheria. For a week after entering the hospital nothing of interest occurred, till suddenly without prodromata the temperature, pulse, and respiration rose simultaneously and severe dyspnœa appeared, which was soon replaced by apnœa, lasting for three hours. Similar attacks occurred during the next few weeks, but a month or two after discharge all paralytic and other symptoms had disappeared. The second of these attacks was the longest, lasting thirty-four hours, during which time, as well as in the other seizures, the child was kept alive simply by uninterrupted artificial respiration performed by Sylvester's method. The author refers the trouble to some post-diphtheritic bacterial poison which inhibited the respiratory centre.

Diet in Typhoid Fever.—James Tyson strenuously upholds the milk diet as being the safest, most satisfactory, and most convenient. Absolute inability to take milk may necessitate a deviation from the rule, but the condition is seldom met with. A tendency to constipation can be counteracted by not boiling the milk, and by the addition of buttermilk, animal broths, especially chicken broth, beef juice, and peptonized foods to the diet. Should evidences of inability to assimilate milk continue to present themselves, there is no more satisfactory nourishment than albumen water. The whites of two eggs to a pint of cold water is an average proportion, and a drachm of lemon juice or brandy or whiskey may be added. The occurrence of hemorrhage calls for the immediate reduction of food. As to the transition to convalescent diet, the author lays down the rule to adhere to liquid food until the temperature has been normal one week. Then he allows a single soft-boiled egg. If nothing happens in twenty-four hours, he allows an egg daily, then, after two or three days, soft milk toast, tentatively, then rice or oatmeal; later, a bit of steak may be chewed or two or three small oysters. Chicken is one of the last foods allowed.

Recent Advances in the Bacterial Treatment of Sewage.—D. H. Bergey describes various systems in use, such as the septic tank, the contact beds, and the coal filter. Professor Claves gives the following advantages of bacterial over chemical treatment: It requires no chemicals, produces no offensive sludge, but only an odorless deposit of sand and vegetable tissue, removes the whole of the suspended matter, and effects the removal of 51.3 per cent. of the dissolved oxidizable and putrescible matter. The resultant liquid is entirely free from objectionable smell, does not become foul when kept, and maintains the life of fish. But as these methods fail to destroy such organisms as the bacillus coli communis, it is safe to believe that they are also incapable of destroying the typhoid bacillus when present. When suitable land is at hand, the effluent of the system of contact beds should be applied to it. Otherwise sand filtration, or electrolysis, or chemical treatment may be used to render the effluent harmless.

Phototherapy in Cutaneous Medicine.—Henry W. Stelwagon gives an account of a visit to Professor Finsen's Light Institute at Copenhagen, where light rays are used for the destruction of the tubercle bacillus in cutaneous tuberculosis. A description is given of the apparatus and of its method of application. The results of the treatment are unquestionably good. Relapses have so far been infrequent and readily managed. The disadvantages are the long duration of the treatment, the cost of the apparatus, the expense of the treatment, and the necessary attention in carrying it out. The Finsen method is practically painless, and appeals strongly to patients with lupus, who have perhaps already been the subjects of repeated curettings and cauterizations. It is probable that the apparatus and technique may be considerably improved in the future, and the duration of the treatment thereby materially shortened.

Successful Removal of Cataracts in Insane Subjects, with Recovery of Mind Attending the Restoration of Sight.—William Campbell Posey reports two cases in which this happy result was obtained. Loss of sight had precipitated loss of mind, and restoration of vision was attended by immediate and permanent return of normal mentality. Such cases are rare, says the writer, but should serve to teach us what may be accomplished by proper measures for the unfortunates who are too often relegated to the list of the hopelessly insane.

The Various Rings Produced in Heller's Nitric Acid Test for Albumin.—By M. H. Fussell.

A Brief Report of a Series of Interesting Cases Recently Seen.—By Alexander Marcy, Jr.

Dublin Journal of Medical Science, December, 1900.

The Operative Treatment of Cleft Palate.—By E. H. Taylor. The operation is thus described: The patient lying in Rose's position under chloroform, the edges of the cleft are pared freely. Blood is removed by a suction apparatus (figured), and throughout the operation sponges are dispensed with as far as possible, pressure with the finger on the bleeding point proving sufficient. A curved incision is now made on each side close to the alveolar margin of the palate, commencing posteriorly inside the last molar tooth, and curving round anteriorly to terminate in the cleft, and arranged at the same time in such a way that sufficient tissue is left immediately behind the incisor teeth to hold a suture subsequently. With this incision the posterior palatine artery is retained in the flap. The latter is reflected by means of a rugine, an instrument which enables one to lift the mucoperiosteal flaps very rapidly and without laceration or serious damage. The next step in the operation is to sever the connections between the hard and soft palate on their nasal aspects. This step is much facilitated by turning back the flaps which have been already detached from the hard palate, and a knife or curved scissors may be employed for the purpose. Silkworm-gut sutures are usually employed. In introducing them it will probably be most convenient to commence behind and come forward. Small curved needles passed with a needle-holder may be used; but, if preferred, a curved needle in a handle may be substituted for them. It is very striking to observe the facility afforded by the mobility of the flaps in carrying out this stage of the operation. At the anterior extremity of the cleft the suture should be passed through the flap from its mucous to its periosteal aspect; the free end of the suture is then carried through the gum, behind the incisor teeth in the reversed direction—viz., from its deep to its superficial aspect. This suture anchors the flap in front during the process of healing. Should it be deemed insufficient an accessory suture passed further out on each side will afford ample security. Difficulty may be experienced in bringing the flaps into apposition at the level of the hard and soft palate, and seeing how unfavorable a high degree of tension is for securing good and rapid union it will be well, following the advice of Dieffenbach, to make an anteroposterior incision in each side, about half an inch in length, at the inner side of the hamular process. The advantages of the operation are thus summarized: 1. It can be performed with greater ease and rapidity than any of the cleft-palate operations with which the author is acquainted. 2. It is not accompanied by troublesome hemorrhage, as no large arterial branch is divided, and whatever hemorrhage does occur may be effectually controlled by digital pressure. 3. The mucoperiosteal flaps have their blood-supply assured. They are raised with the least possible damage; and this is a material advantage when dealing with the delicate and friable tissues of young children. 4. The free range of mobility of the flaps facilitates in a very marked way the introduction of the sutures; more especially is this the case at the anterior extremity of the cleft, which has hitherto been a difficult part to close. 5. Lastly, the operation is well adapted to young children. One of the main difficulties with them is the carrying out of the post-operatory details. A skilled nurse can do a great deal to promote a favorable result, and a few days before operation spent in making friends with the little patient will have a telling effect on the subsequent course of events.

Fracture of the Pelvis.—E. H. Bennett describes the findings in three cases, the bony specimens from which were presented by him at a recent meeting of the Royal Academy of Medicine in Ireland, section on pathology. His contention is that these injuries are not necessarily fatal, though of course always grave.

Bodies in the Urine in a Case of Blackwater Fever.—E. G. Hamilton Williams and Mary Hamilton Williams describe as follows bodies found by microscopical examination in the urine in a case of blackwater fever. (A) A body of an elliptic or round contour, showing a refractile spot with a central dark spot; the rest of the body finely granular or containing fine vacuoles stained faintly blue, with a distinct margin. (B) Far more numerous bodies, round or elliptic in contour, staining deep blue, with an indistinct margin, surrounded partly or completely by an irregular area of some substance stained less deeply. In the second day's urine the number of bodies was smaller; the third day's urine showed a few bodies (C) elongated in shape. On the eighth day some bodies (D) were seen, somewhat pear-shaped, with a dark spot placed laterally on the side of the pear, and partly surrounded by a clear space. The question arises: Are any or all of these bodies organisms connected with the disease? The large numbers found of A, B, and D make it appear to the writers probable that they are not accidental, but it is mostly the similarity in structure of the bodies marked C which make any

relationship of these likely. Are the bodies described various stages in the life of an organism, and, if so, is it pathognomonic of blackwater fever?

Some Difficulties in Dealing with Liver Abscess and How to Obviate Them.—Neil Macleod describes his methods of aspirating and of operating. The objects to be kept in view in dealing with these abscesses are: 1. Aseptic, free drainage of their contents. 2. To provide the shortest drainage track emerging at a point in the abdominal or chest wall, preferably in front or laterally. 3. If the liver is not adherent to the wall of the abdomen at the point of puncture, to prevent leakage of the contents into the pleural or peritoneal cavities, and to maintain opposite each other the openings in the organ and wall during the operation. 4. To anchor the liver securely at that point, and create adhesions if they are absent. 5. To do no more damage to the soft and bony tissues than is absolutely necessary to secure these ends, with as little hemorrhage as possible. 6. To keep the drainage tract open until the abscess cavity has contracted all round the drainage tube, and discharge has ceased.

Pani Ghao, Water Sore, Commonly Called "Sore Feet" of Assam Coolies.—An anonymous writer says that during its season, from May to October, more coolies are laid up from this cause alone than from any other, with the exception perhaps of malaria. The disease is not fatal, but causes great pain and discomfort. The first symptom is intense itching, with a little pain, which increases on the second day, when an eruption begins to appear and the foot swells. Walking becomes painful. The eruption may occur in one of three forms, the vesicular or pustular, the herpetiform, and the interdigital. It occurs only in those who walk slowly about with naked feet on the bare, loose cultivated soil. Treatment is surgical and preventive. The wearing of clogs would decrease the number of cases to a certain extent, but the difficulty lies in inducing the coolies to wear them, as they hate new customs and learn them with reluctance.

Goundon and Ainhum in South China.—J. Preston Maxwell describes the case of a man who came to him suffering from a condition precisely similar to ainhum. His left little toe was swollen and nearly surrounded by an ulcerated groove, the ulceration showing some tendency to spread more widely on the plantar aspect of the foot. Anæsthetic patches appeared later, and from one of them a bacillus resembling the leprosy bacillus was obtained. There is no doubt at present that the man is a leper, and the author raises the question as to whether there may be a connection between ainhum and leprosy. The illustration of the case of goundon shows a woman with two symmetrical swellings situated one on either side of the nose. The swellings are hard, painless, and the skin over them is movable and natural. The disease began when the patient, now forty-five years of age, was a girl, steadily progressed for some years, is now entirely stationary, and the woman appears to be in good health.

The Treatment of Night Blindness by Ingestion of Liver.—W. J. Buchanan has treated some twenty cases, with great and immediate success, by giving about eight ounces of liver (goat, sheep, or ox) fried in oil and with spices, daily, for a few days. Usually he finds that five or six days are sufficient to effect a cure, but he usually continues the treatment for at least a week. Under the ordinary tonic treatment such cases are not even improved under two or three months. It seems probable that the liver acts somewhat after the fashion of thyroid and suprarenal extract, and the other substances used in organo-therapy. The immediate good effect cannot be due solely to any nitrogenous element in the food, for an equal quantity of fresh meat is useless. The night-blindness meant is the common form so often found in malarial or scorbutic cachexias; not that due to retinitis pigmentosa, which is a rare disease.

Malarial Ulcers in British Central Africa.—David Kerr Cross says that the first indication in the treatment of fever sores is bodily rest in the horizontal position with elevation of the limb. The next, realizing that we have to do with a phagedenic sore and bacilli and dead tissue, is to annihilate these deleterious influences by the actual cautery, or other strong caustic, as pure carbolic acid. The author usually gives the natives chloroform and scrapes away the false membrane and dead tissue, and freely swabs with carbolic acid. In a few days a healthy-looking sore, free from all putridity, is the result. The wound is dressed with some one of the excellent antiseptic dressings. A creamy-looking powder made of one part iodoform to three of boric acid, dusted on these wounds, acts like a charm on the natives. These measures must always be accompanied by tonics, as iron, arsenic, quinine, and strychnine.

Notes of Blackwater Fever as Found on the Congo (Mid-Congo State).—Charles B. Banks is inclined to believe that blackwater is only a complication arising in the course of a remittent fever, and should be treated as such. He thinks it is often a result of sudden congestion of the kidneys, sometimes kept up and aggravated by such drugs as quinine, antipyrin, and phenacetin. His reason for believing this is that he has always found that it ceases when steps have been taken thoroughly to relieve the kidney, and hæmostatics given. He has sometimes used ergot externally with good effect, although the temperature usually rose a little after its use. He has noticed that it is usually persons of a nervous temperament, also those of a gouty or rheumatic diathesis, who are most prone to have blackwater fever, and it usually comes on after a time of worry or anxiety.

Mosquito-Screened Houses versus Quinine.—A. H. Hanley says that although it has been proved that the use of the mosquito net on the Campagna prevents malaria, any one going to Southern Nigeria and expecting to steer clear of fever by its use at night will be disappointed. The anopheles here attack both by day and night. In the author's practice he has had to take long journeys in a boat at night, and for twenty-six miles has been exposed to the attacks of mosquitos and other pests, but thanks to ten grains of quinine taken either when starting, or on his arrival, has for years escaped fever. He cannot speak too strongly of quinine as a prophylactic, and he deprecates the tendency to put the quinine bottle aside and depend on the mosquito net, which used only at night confers but partial protection.

The General Care of the Skin, Considered from the Point of View of Prophylaxis.—W. Allan Jamieson says that one port of entrance by means of which the ubiquitous microbe finds its way into the body is by the skin, but in a sound and healthy state the integument presents an almost impassable barrier to micro-organisms. To maintain the surface of the skin in the best possible condition, the writer advocates cold baths, the use of less soap than is the custom, or the use of neutral soaps, and friction with the loofah. Warm baths should be used in great moderation. The nails require care, to prevent them from carrying infection. They should be kept short and cleaned by means of a nail brush and soap and warm water, not metal files or knives. To disinfect the hands themselves, they should be smeared over with kaolin or, better yet, with emolkeleet to remove the surface fat, then washed in an infusion of bran with green soap and warm water and a nail brush; and then dried with friction by a rough towel.

Dental Caries as a Factor of Disease.—J. R. Leeson dwells upon the fact that unclean mouths and decaying teeth cause many diseases whose etiology is little understood. The mouth cavity acts as a first-rate incubator, and, by its moisture, heat, and darkness, supplies the microbe with all that it can desire to breed its innumerable progeny. Cases of anæmia, general debility, neuralgia, indigestion, tetany, hysteria, chronic gastritis, etc., may all be due to carious teeth. Diseases of the gums, tongue, tonsils, larynx, oral and nasal pharynx, nose, and even middle ear are found to consist of chronic congestions and inflammations of their mucous membranes. How much of all this trouble is caused by the constant invasion of these regions by the septic organisms of contiguous carious teeth we are only beginning to realize. Absolute mouth cleanliness and the watchful care of a good dentist are necessities to health.

Observations on Tuberculosis by a General Practitioner.—Hirsch attributes much of the non-success of our efforts to

restrict the spread of the disease to the difficulty experienced in getting patients to realize the gravity of their condition while the malady is still in its earlier stages, and their reluctance to submit themselves to the systematic and preferably institutional treatment which alone affords any hope of cure. It is the duty of the physician to inform the patient of the possible presence of tuberculous infection just as soon as it is even suspected, and though the news may come as a shock to the patient his co-operation in any line of treatment is thus assured, and greater attention will be paid to details of hygiene and daily life, so that permanent cure may be reasonably hoped for. The main lines along which the disease is to be attacked are those of diet and general hygiene, but the almost universally prevalent custom of enforcing large meat consumption is ill advised. The poorly balanced system of the tuberculous subject reacts with too great intensity to the highly stimulating properties of such a diet, and especially in those predisposed to hemorrhage the consequences are often distinctly unfavorable. Alcohol, likewise, is not to be regarded as adapted for habitual use, since in such patients the oxidation processes suffer great reduction, owing to the diminution in lung capacity. As a result of actual observation on a large number of patients it was found that the omission of alcohol from the regular medication was followed by better appetite, greater increase in weight, and less fluctuation of the temperature.

The New Norwegian Statute Controlling the Institutional Treatment of Tuberculosis.—M. Holmboe reports the provisions of this law, which are essentially as follows: All cases of tuberculous disease of such nature as to make the danger of infection possible are to be reported to the sanitary commission by the attending physician, who has also to give proper directions to prevent the spread of the disease. If these are not complied with, or the patient is without medical attendance, the commission has the power to direct his removal to a suitable institution. Persons suffering from such disease are not to be permitted to engage in any business which involves the handling of food products nor to take positions as wetnurses or children's maids.

How does Infection of the Intestine Take Place?—Buttersack is of the opinion that the direct localization of tubercle bacilli in the intestinal mucosa, while possible, is infrequent. If the infectious matter be swallowed during or shortly after a meal the digestive juices and active peristalsis do not give the invaders much opportunity to gain a foothold, but during the period of physiological rest infection may sometimes occur. The mesenteric glands occupy the same position in regard to the intestinal tract that the bronchial glands do to the lungs, and it is usually only after these have become infected and their powers of resistance overcome that involvement of the gut takes place.

The Demonstration of the Tubercle Bacillus in the Sputum.—Czaplewski calls attention to the fact that, in the usual treatment of sputum with an uncontrolled amount of caustic soda solution preparatory to centrifuging, there is danger of diminishing the staining-power of the bacilli. His method is to add 0.2 per cent. soda solution and heat under constant stirring. As soon as liquefaction ensues a few drops of phenolphthalein solution are added, giving a red color. Ten per cent. acetic acid is now added drop by drop till the color is discharged, *i.e.*, the mixture is neutral, and centrifugal sedimentation proceeded with as usual.

Tuberculosis in Roumania and the Means of Combating it.—According to Babes, Roumania has not yet had to suffer greatly from tuberculosis, and he therefore considers it an especially favorable country for the inauguration of stringent sanitary regulations. He outlines a system of legislation which shall control mortality and morbidity statistics, public sanitation and education, etc.

On the Treatment of Tuberculosis by Sodium Cinnamate.—By Alfred Mann.

Tuberculosis, Blood Supply, and Blood.—By H. W. Blöte.

Zeitschrift f. klin. Medicin, vol. xli., Nos. 5 and 6.

The Stokes-Adams Syndrome.—August Hoffmann's case furnished opportunity for a careful investigation of the nature of this rare symptom complex, which consists in slowing of the pulse, attacks of unconsciousness, and respiratory disturbance. By a study of the pulse tracings obtained, together with combined auscultation and fluoroscopic examination continued over a period of several hours, the author reached the conclusion that the bradycardia was due to diminished conductivity of the heart muscle itself, whereby the normal contractile impulse which originates at the venous ostia of the auricles is impeded on its way toward the apex, and therefore, while the auricles may be making several contractions, systole of the ventricles occurs but once. The causes of this inhibition of conduction may be various, though the disease is most frequently found in those of advanced years who are suffering from fatty degeneration of the heart, arteriosclerosis, myocarditis, or other cardiac myopathies, while it has also been observed in disease of the spinal cord, vagus, and even in purely functional affections. The assumption is that the simple nutritional disturbance of the heart muscle accompanyiug the anæmia is sufficient to produce the disorder. In the author's case the daily inhalation of thirty litres of oxygen seemed to cause marked improvement, though this conclusion is not wholly free from *post hoc ergo propter hoc* reasoning.

Metabolism in the Obese.—Jaquet and Svenson report on a series of observations made on patients of the adipose habit to determine whether in addition to those cases of obesity ascribable to excess of food with a deficiency of muscular work, there are others in which there is restriction of the physiological oxidation processes. Basing their calculations on a study of the gaseous interchange of respiratiou, they found that in the fasting state the subjects examined did not vary from the normal, while they did not react sufficiently to the ingestion of food. The rise in gaseous interchange is less and is of shorter duration than is the case in average individuals. A not inconsiderable saving of fuel is the natural sequence, and at least a part of the fat accumulation is explicable on this ground. The reaction to muscular activity in the corpulent appears to vary according to the condition of the organs. In one case the results were much like the normal, while in another very slight muscular action was followed by a very great increase in oxygen consumption. The beneficial effect of thyroid extract in such patients may be referred to two factors. In the first place, in one series of experiments the loss of water alone was sufficient to account for the result, while there may also be an increase in oxidation, though this was observed only after the taking of food.

The Prognosis in Aortic Aneurism.—Kotowtschicoff is inclined to consider this affection more optimistically than most clinicians. Assuming that in most cases it is of luetic origin and due to inflammatory processes in the substance of the vessel wall, the proper antisyphilitic treatment should check the inflammation and therefore also bring the dilatation to a standstill. Eight cases are reported, four of them offering indisputable evidence as to the nature of the lesion, while in the others it was only presumptive. In all of these potassium iodide in large doses produced most gratifying results, the pulsating tumors were reduced in size, laryngeal palsies were cured, dulness on percussion was obliterated, subjective symptoms were relieved, etc. Evidence of incipient iodism is not an indication for cessation of the treatment, and the drug should be pushed to the very limits of tolerance.

Amatus Lusitanus and His Day.—By M. Solomon.

Revue de Chirurgie, October 10, 1900.

Intestinal Juice in the Treatment of Intestinal Occlusion.—E. Vidal says that the purely mechanical conception of intestinal occlusion is no longer found satisfactory. The important factors of the condition are now recognized to be the stasis of septic and toxic substances in the intestinal tract, an increase in virulence of the bacteria within the strangulated loops, and a disappearance of the defensive agents with consequent penetration of the coli bacillus, and resorption of the active microbial toxins and putrid poisons. Stercoræmic infection is the usual cause of death in these cases. The author holds that the injection of intestinal juice will neutralize poisons already in the circulation and in every way take the place of the normal secretion which has been impaired. His experiments on animals bear out his theory. Unfortunately, in the case of two patients, treatment was begun too late to save life, but many symptoms were so markedly relieved as to indicate happier results in cases treated in time.

Suture of Heart Wounds.—F. Terrier and E. Reymond thus conclude an article giving a detailed description of the various operations used for heart wounds: (1) A flap opening outward appears to be the best in the majority of cases. (2) When possible, it is better to push the pleura aside to reach the pericardium, rather than to go through it. (3) A continued suture is better than separate stitches in

closing heart wounds. (4) Neither pleura nor pericardium (more especially the latter) should be drained, but whenever possible should be completely closed.

Cancer of the Large Intestine, with the Exception of the Rectum.—By R. De Bovis. A continued article.

Sub-Pyloric Gastroduodenostomy.—By Eugène Villard.

Revue de Médecine, October 10, 1900.

Trophic Disorders and Disorders of Sensation in Hemiplegia.—P. Chatin, from a study of a number of cases, concludes that trophic and vasomotor disturbances are of frequent occurrence in hemiplegia, and are usually more marked in the upper than in the lower extremity. Disorders of sensation, whether subjective or objective, are also almost constantly present. Motor troubles alone may be accompanied by the symptoms of dystrophy, but when motor and sensory disorders are found together, there is much more probability of their being followed by atrophy. In other words, double lesions of the reflex arc are more often accompanied by trophic disorders than are simple lesions. The conclusion to which the author leads is that muscular atrophy is the result of the simultaneous impairment of sensory functions on the one hand, and motor and vasomotor functions on the other hand.

Family Spasmodic Paraplegia and Family Disseminated Sclerosis.—R. Cestan and G. Guillian believe that these two affections, in spite of their evident clinical resemblances, do not belong in the same morbid group. Disseminated sclerosis they hold to be a true clinical syndrome. In order to decide whether a given disease is a family affection, several points are to be borne in mind: (1) The disease must, in unchanged form, affect several children belonging to the same generation. (2) Its onset must occur at about the same time in each. (3) It must be clinically independent of all external influence, of any acquired disease, or of any intra-uterine accident. (4) These various characteristics must be the rule and not the exception.

Simple Persistence of the Arterial Canal.—By G. Gérard. A continued article.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

BEER, ARSENIC, BERI-BERI—MEDICAL COUNCIL, FINANCES, DUBLIN APOTHECARIES' HALL—THE NATIONAL HOSPITAL FOR PARALYSIS, ETC.—ADDENDUM TO B. P.—NON-MALIGNANT CANCER—FEMALE INTEMPERANCE—OTOLOGICAL SOCIETY—OBITUARY.

London, December 14, 1900.

Beer still holds the field as the topic of the week. Pure beer, poisoned beer, malt and hops beer, substitute beer, glucose, invert sugar, arsenic—these are the words that crop up in almost every conversation. Nor is it to be wondered at, considering the widespread danger. Great dissatisfaction and suspicion have prevailed in consequence of the adjourned inquests, but these feelings were somewhat allayed by the announcement that Dr. Seaton Buchanan was despatched by the local government board to investigate the outbreak of peripheral neuritis. It is probable that further inquiry will take place.

The coroners have declared that there will be no suppression of facts at the adjourned inquests, and it seems a pity they should have been put off for so long a time—until January 9th. However, at that date we shall probably have a good many facts requiring digestion.

Meantime the brewers are very active in culling out their products and emptying contaminated samples down the sewers—thus preventing the spread of the epidemic, say some; nay, destroying the evidence against them, retort others. Of course, the brewers are anxious, for their responsibility must be great whatever facts may transpire. They have appointed a committee of experts, including two official analysts, but it was stated in the House of Commons last night that these gentlemen are not acting on behalf of the Home Office in this matter.

A number of summonses have been taken out by the local authorities against the retailers of the poisoned beer for selling what was not of the nature, substance, and quality of the article demanded, to the prejudice of the purchasers. This would seem to be a way to get at the brewers, for it would certainly be hard to punish mere retailers. It seems there is some difficulty about taking samples at the breweries, and, moreover, the contaminated products have mostly been destroyed.

A curious attempt to exploit the epidemic is the offer of an insurance company to issue policies indemnifying brewers against legal liability arising out of arsenic being found in their beer. Perhaps this is chiefly a cover for a further offer to insure individuals against death brought on by poisoned beer.

Among interesting points connected with the cases of arsenical neuritis is the similarity of the symptoms to those of beriberi. In fact, as I told you, some cases had been attributed to that disease. I conjectured that some epidemics supposed to have been beriberi might have arisen in such a way. And now no less an authority on tropical diseases than Ronald Ross, after examining a number of the cases in Manchester and Chester, says that if the cases had occurred in a beriberi region few medical men would have failed to consider them such. He remarks that on other grounds it has long been thought that food-poisoning may have to do with beriberi, and there are many points that suggest intoxication rather than infection.

Before the Medical Council closed its long session there was the report of the finance committee to consider. According to some the accounts require complete revision and economy must be enforced. The report shed little light on the subject, and after much talk a professional accountant is to look into the matter, which is, therefore, again postponed.

Another dead-set was also made on the Dublin Apothecaries' Hall through the report of the examination committee, which reflected on their inspector and suggested that the hall had not the power to appoint examiners in certain subjects. The hall is prepared to fight that question in the law courts. One cannot blame them for that. There is no need whatever for the existence of the hall, and I think it would be well if its powers were annulled, but it is not to be got rid of by a side wind; nor are unfair criticisms and reiterated reproaches from representatives of hostile corporations likely to lead it to give up rights under charters or acts of parliament.

The management of the National Hospital for Paralysis and Epilepsy is still a subject of dispute. The board, which proceeded to appoint an arbitrator, has had another fall. At the opening of the inquiry on Monday the "court" was informed that the staff declined to recognize it—as it was appointed by one party to the dispute and the most important points were excluded from its cognizance. Result: adjournment *sine die*. The board will have to give in. If the dispute is satisfactorily settled before May 1st, the Sunday fund will grant an award; otherwise, perhaps nothing for another year. The draft of the promised *addendum* to the pharmacopœia was presented to the council at the late session and will soon be in the hands of those who feel any interest in it. It contains fifty-four drugs and sixty-five preparations. Some of the names are not unfamiliar to prescribers in this country, though a large proportion come as almost or quite strange. The *addendum* is really an extension of the appendix, which authorized for local use certain preparations employed in India and the colonies as substitutes for drugs in the B. P. Of course, it is not intended that dispensers may substitute one for the other, but that prescribers must be guided by their own judgment as to the value of alternatives for older remedies. This recognition of the value of medicinal products of India and the colonies is expected to lead to further investigations into their value in the localities where they are found.

"Non-malignant cancer" sounds like a contradiction in terms. Yet that was the name applied to a case of cancer of the breast related to the Pathological Society by Dr. S. Bontor. Perhaps quiescent or stationary would be a more appropriate name for such cases. Carcinoma in the aged is of slower growth than in younger patients, and sometimes seems to stand still for long periods. This seems to have been so in Dr. Bontor's patient, and the case is not unique though unusual. His patient died of asthenia at the age of seventy-seven, having had a lump in the left breast for twenty-three years. It never gave her pain, though latterly she felt a sense of constriction of the chest. There were some secondary deposits in the right breast and in the skin over the abdomen, but no enlarged glands, no signs of distant organs being affected. Most cases of chronic cancer end in extension. After remaining stationary for years, they suddenly take on active growth and ulcerate. Dr. Bontor's case seems to have remained quite quiescent even when the patient sank from asthenia. But both macro- and microscopical appearances showed the growth to be cancerous.

The president (Mr. Watson Cheyne) remarked that the case seemed to be a typical one of atrophic scirrhus which had lasted a long time, but was not otherwise remarkable except that there was no involvement of internal organs. He recalled a case which lasted fourteen years and then a sudden outburst took place, and another in which after nine years rapid extension followed an attack of influenza.

Mr. Balance mentioned a case in which cancer appeared in both breasts at the age of seventy, but did not affect the general health of the patient, who lived on to the age of eighty-two.

The British Medical Temperance Association has had a debate on the increase of drunkenness among women, and has adopted a resolution to the effect that grocers' licenses promote female intemperance and ought to be abolished.

The Otological Society has held its first annual dinner, at which the presidents of the leading societies were present and welcomed their juvenile sister into their family. Dr. Pavy, of the Medico-Chirurgical, described the meeting as the christening ceremony. The otologists seem full of hope for the progress of their branch.

Dr. G. H. Milnes, a distinguished Cambridge graduate, physician to the Derbyshire Infirmary, died on the 20th ult. from an overdose of morphine, subcutaneously injected by himself. He was in the naval service from 1886 to 1890, and held the Egyptian war medal with clasp and the Khedive's star.

The deaths are also announced of Dr. A. D. Davidson, ophthalmic surgeon to the Swansea Hospital, aged fifty-one years, on the 7th inst.; Dr. H. G. Rawdon, surgeon to the Southern Hospital and Children's Infirmary, Liverpool, aged sixty-four years, of cerebral hemorrhage; A. E. Elliott, M.A. Cantab., M.R.C.S., etc., civil surgeon to the Field Force, South Africa, on December 1st, of enteric fever.

THE SELF-LIMITATION OF INFECTIOUS DISEASES.

To the Editor of the Medical Record.

Sir: In your issue of December 8, 1900, I find an abstract from the *Indiana Medical Journal* in which J. O. Malsbury gives utterance to the belief that micro-organisms are governed by that law of nature which holds good for high animal life, viz., that to the constant interbreeding and the resultant loss of vigorous procreation is due the early death of the organisms producing the disease, and consequently the self-limitation of that disease. This may be partly true, but seems to me to be rather far-fetched, and by applying another law governing high animal life to the lower types, let us see if we cannot approximate a conclusion which seems more plausible. Given a certain area of ground which furnishes a limited number of persons perfectly healthy media of life, fresh air, pure water, drainage, and sufficient food, and we will have, barring accidents, a comparatively healthy community. Take now the same area and in its space crowd together ten, twenty, or even a hundred times the number of inhabitants, and what is the result? The air becomes vitiated, the water contaminated, drainage defective, and the very soil polluted; disease manifests itself, and unless the conditions are speedily remedied, life itself would soon cease to exist. In this case it is not the interbreeding which checks the vigor and procreation of our community, but the decomposition products of animal life, which render the air unfit to breathe, water unfit to drink, and the very soil, on the whole, incapable of sustaining life. As the above holds good in high animal life, so it does in high plant life: any crowding together of a large number of plants is punished by either distorted and poor growth or a complete failure of the plants to come to maturity. Here, again, it is not the interbreeding which does the harm, but the close herding, which does not allow the individual plant to obtain its required amount of carbon dioxide (CO_2), sunshine, the moisture and salts of the soil necessary to sustain life, and so life becomes self-limited.

And this law also governs low plant life; given a culture of any micro-organism, if we place the same under proper conditions for growth in a short time we shall find that our culture has ceased to be reproductive and a little later becomes even harmless. It is not the interbreeding which produces this effect, for we can keep a culture virulent and even increase its virulence if we add fresh material to our original culture medium. No matter how large the growth and number of the organisms present, their number and virulence will increase if we can only supply sufficient media for them to grow on. It is the product of tissue metabolism evolved by the organism during its life history which does the harm, or rather in this case the good.

Every organism in its growth produces toxins and antitoxins, either one of which may be inimical to its own well-being, and it is only a question of time, if new soil is not added, or if the abstraction of these poisons is not provided for, when the soil will be rendered unfit for further growth and the culture dies. The same conditions hold good in disease and especially in the infectious fevers. Infection having taken place, if the soil is suitable, multiplication of the organism ensues until all the available soil is occupied. Then the crowding begins and with it a decline in number and virulence of the micro-organism. Multiplication has been going on at an enormous rate, the decomposition products of metabolism are being constantly set free from these minute units of life, in their birth, growth, reproduction, and death, and the result is that unless new soil is invaded a sudden check is put upon the growth and life of the organisms by the very poisons which they have produced to the detriment of the host they inhabit. Pneumonia is a disease which exemplifies the above. After infection has taken place we have the incubation period lasting a variable length of time, during which period the micrococci of Fränkel are multiplying and producing their toxins and antitoxins. Suddenly the patient has a chill; this is the sign that the system is becoming surcharged with the toxins, an inflammatory reaction now sets in which endeavors to limit and localize the infection, namely, by consolidation. This being successful the organisms are hemmed in, and reproduction continuing, crowding and its consequences result, and the death of the pathogenic germs is soon manifested by the crisis. If the hepatization is not effective in isolating the points of infection, then new areas are constantly involved, the crisis does not appear, the patient becomes surcharged with the toxins from the constant absorption, and death soon ends the scene.

The same thing occurs in typhoid fever, only much more slowly, as the bacillus of Eberth does not produce so intense an inflammation in the intestinal tract, and consequently isolation and localization do not occur so rapidly. New areas are constantly infected until either all the available soil has been invaded or the inflammatory wall checks the spread of the organism; then the decline in the fever begins as the bacilli have begun their own destruction. The lesions of typhoid in the intestinal tract explain to a great extent why we do not get a crisis in this disease. The lymphatic tissue is soft, absorption is great, and the inflammation produced by the typhoid bacillus is not sufficiently severe to produce the rapid isolation of the infected area, such as happens in pneumonia; consequently, while one area is being surrounded by the protecting wall of inflammation, new areas are freshly infected, and this continues until either tissue is reached in which sufficient inflammation is produced to limit the further extension of infection or until all the soil suitable for the propagation of the organism has been invaded. Judging from all this, the belief seems reasonable that it is not the interbreeding which limits the life of these death-dealing organisms, but mainly the fact that when placed under conditions suitable for growth they will propagate so rapidly that unless sufficient new soil is added from time to time the toxins and decomposition products they produce during their life will become powerful enough to end soon their existence and so self-limit the disease they have produced.

R. Hertzberg, M.D.

Stamford, Conn.

The Effect of Mastication in Influencing Gastric Secretion.—Max Schreuer and Alfred Riegel, in order to determine in how far the secretion of gastric juice was influenced by the mastication of the food, gave test meals of various composition and then examined the stomach contents after longer or shorter intervals of time had elapsed. The food was given in various ways; being chewed and swallowed as usual, or artificially subdivided and put into the stomach through a tube, or being chewed and then expectorated without swallowing. The results showed that the act of mastication is capable of directly modifying the activity of the gastric glands and that this is independent of the chemical stimulation produced by the saliva swallowed. When the material tested consisted of carbohydrates it was found that the exclusion of mastication was followed by a more or less considerable deficiency in the hydrochloric-acid values, while when the meal consisted of proteids (meat, hard-boiled eggs) the normal or hyperacid stomach reacted differently from one in which subacidity was present. In consequence of the greater degree of stimulation produced by these substances, the normal or hyperacid stomach is able to compensate for the HCl deficit attending the omission of the act of chewing, while the subacid stomach is not capable of this but shows marked variation from the normal after the reception through a tube of artificially masticated food.—*Zeitschrift für diätetische u. physikalische Therapie*, No. 6, vol. iv., 1900.

Society Reports.

THE PRACTITIONERS' SOCIETY.

One Hundred and Fifty-ninth Regular Meeting, Held on Friday, December 7, 1900.

A. Alexander Smith, M.D., President, in the Chair.

The Prevention and Relief of Post-Operative Intestinal Obstruction.—Dr. Clement Cleveland read this paper (see page 1).

Dr. George L. Peabody said that while he did not feel competent to comment upon the surgical aspect of the procedure suggested by Dr. Cleveland, it interested him as furnishing a good illustration of the value of empiricism in medicine. It would be rather difficult to explain, however, how the oxygen gas could exert anything more than a mechanical effect, unless, perhaps, it stimulated peristalsis, as suggested by Dr. Cleveland. There was probably no absorption of the gas. It must satisfy its chemical affinities locally on the mucous membrane or on colon contents, and at once cease to be oxygen in consequence.

Dr. William M. Polk said he was glad to learn of this simple and apparently efficient method of treating cases of post-operative intestinal obstruction. This complication was often a very trying one, and its treatment by catharsis had not proved very satisfactory in his hands.

Dr. William T. Bull said that all surgeons were familiar with the trying situation which might arise after abdominal section, when the bowels refused to respond to enemata or cathartics, and Dr. Cleveland had suggested a possible resource, which, in his hands, seemed to have been very effective. He was disposed to criticise Dr. Cleveland's notion that these cases of post-operative intestinal obstruction were purely of a mechanical nature, and were unaccompanied by peritonitis. In spite of the fact that there might be no elevation of temperature, there was probably in these cases a plastic peritonitis which sometimes yielded if we ceased in our endeavors to promote peristalsis by cathartics and enemata. The speaker said that, in his own practice, when the obstruction failed to yield to ordinary methods, he went back to the old-fashioned opium treatment with cold applications over the abdomen. In some instances the obstruction had yielded to the latter method, after catharsis had failed. Dr. Bull said he wished to mention another way of relieving tymanites after abdominal operations, in cases in which no peritonitis was supposed to exist. It was suggested by a surgeon in the West, and termed by him the "postural" method. It was particularly useful after operations on the liver or gall bladder, which were likely to be followed on the first or second day by vomiting and tympanites without elevated temperature or other symptoms of peritonitis. At such an early time one did not want to administer cathartics, and the postural method referred to often gave very satisfactory results. It consisted in elevating the patient's pelvis as high as possible or putting him in the knee-elbow position; this placed the outlet of the alimentary canal much higher than the inlet, and gas was found to escape freely. The explanation suggested by Dr. Cleveland seemed rational. Other gases besides oxygen ought to accomplish the same purpose if the effect was a mechanical one, and one ought to succeed just as well with air or hydrogen gas.

Dr. Joseph D. Bryant said that but few cases of post-operative intestinal obstruction had come under his observation. He could recall only three. In one, after a futile attempt to move the bowels by enemata, he kept the patient quiet and administered small doses of opium, and the result was entirely satisfactory. In another instance an enema preceded by a dose of calomel was sufficient. The same treatment was satisfactory in the third case. As bearing upon this subject, Dr. Bryant reported the following case, which he had seen casually about a year ago. The patient had been operated on outside of the city for appendicitis. Two or three weeks later he developed pain in the appendicular region and symptoms indicating obstruction, particularly as intestinal peristalsis could be seen extending down to the lower portion of the ileum, and disappearing at the point where the pain occurred. The method employed to relieve the obstruction consisted of the introduction into the lower bowel of carbonic-acid gas and a small-sized hand, and then an electrode was carried up with the idea of influencing the supposed adhesions by the electrical current. The patient eventually recovered.

Dr. Beverley Robinson said that experiments had shown that in some cases the ileo-cæcal valve would permit of the passage of fluid from the cæcum to the ileum, while in others it would not. In a recorded case of supposed volvulus, the injection of fluid into the bowels was followed by a gush of the fluid from the child's mouth, and the subsequent disappearance of the volvulus. It had also been shown that hydrogen gas injected into the bowels might escape through the mouth.

Dr. Peabody said he had seen oil given per rectum vomited by the mouth.

Dr. V. P. Gibney asked Dr. Cleveland why he waited forty-eight hours before resorting to the injection of oxygen. If there was no objection to its use, why should it not be given earlier, without resort to enemata or cathartics?

Dr. Cleveland, in closing, said that in one of his cases he resorted to the use of the oxygen gas soon after the symptoms of obstruction became apparent. The reason he had not done so in all of his cases was that he still looked upon the procedure in the light of an experiment, and his chief experience with it was recent and limited. In the future, he intended to resort to it without delay. The gas was injected from an ordinary hospital cylinder, and its force was checked by first passing it through a bottle of water. The injection was made very slowly, and was stopped when the patient complained of pain and distention.

A Case of Æstivo-Autumnal Fever with Unusual Symptoms.—Dr. George L. Peabody reported this case (see page 3).

Dr. E. G. Janeway said he had recently seen a case of æstivo-autumnal fever in which the abdominal pain was so severe that a diagnosis of appendicitis had been made and an operation was under consideration. There were also vomitings and tenderness over the right side of the abdomen with sensitive skin, but no rigidity of the rectus muscle was apparent. The first blood examination failed to indicate the presence of an inflammatory process, only a single malarial parasite was discovered, the leucocyte count was 5,500, and no Widal reaction was present. The second blood examination was absolutely negative. At a subsequent examination, made at the Presbyterian Hospital, a few malarial organisms were found. The vomiting was so severe that quinine could not be given by mouth for diagnostic purposes. The case eventually proved to be one of malaria of the æstivo-autumnal type. Dr. Janeway said it was a mistake to assume that the spleen enlarged only downward. It might also enlarge upward, forming a tumor underneath the thorax, and still there might be no adhesions. These cases he had seen cause mistakes in diagnosis.

Dr. Robinson inquired whether the æstivo-autumnal

type of malaria was very rare in New York City. The speaker said he had seen one such case this year, which he thought had originated here.

Dr. Walter B. James, in answer to Dr. Robinson, said that this type of malaria had been rather rare in New York in past years. The cases that were seen here usually originated at a considerable distance from the city. Recently, however, the speaker said, he had seen a number of cases which apparently originated in this neighborhood. He recalled one case which apparently originated at City Island and another at College Point. A possible explanation for this fact is that a large number of patients suffering from æstivo-autumnal fever were brought to this city after the Spanish War, and it is not unlikely that in this way the peculiar organism causing this type of malaria found a foothold in this neighborhood and might become endemic. Dr. James said that the clinical features of æstivo-autumnal fever differed widely in different cases, and in some instances the organism in the blood must be searched for very diligently before it was discovered, as in the case mentioned by Dr. Janeway. In some cases the most pronounced symptom was the prostration, with perhaps very low range of temperature and a moderate degree of anæmia. The diagnosis could sometimes be made only after repeated examinations of the blood by one skilled in this particular line of work.

Dr. Robinson said that while this was generally regarded as a grave type of malaria, the symptoms were not severe in the case he had seen.

Dr. Janeway said that in the case he referred to the symptoms were very severe at first: the fever was high and there were indications of profound sepsis.

Dr. Peabody said he had had under observation four cases of æstivo-autumnal fever, and in none of them did the symptoms bear a very close resemblance to each other, although they had all had a continuous fever, not of a high grade. In three of them the original diagnosis was typhoid fever, on account of the marked prostration and continued fever. In one of them the blood gave the Widal reaction, but all of them had crescents in their blood, and all promptly recovered under quinine.

Dr. Robinson said that some patients objected to having repeated blood examinations made.

Dr. A. A. Smith thought there was less objection to this now than formerly.

Dr. Janeway said some complained if their blood was not examined.

A Case of Appendicitis with Diffuse Pelvic Exudate.—This was reported by Dr. William M. Polk. The patient was a woman who, upon examination, presented a very well-defined mass on the right side, extending well down into the bottom of the pelvis and involving the whole of the right broad ligament. The uterus was fixed and pushed over to the opposite side, and there was an exudate between the bladder and uterus which extended for some distance toward the left side. The patient was an ignorant Italian, and it was impossible to get a clear history of her previous condition. When the abdomen was opened, the appendix was found lying bent upon itself, with the knuckle resting well on the base of the broad ligament. Its free end was adherent to the broad ligament and extended upward between the ovary and uterus; upon its anterior face there was an ulceration which had, in turn, produced an ulceration and perforation of the broad ligament, and led to the production of an extensive anteperitoneal exudate between the bladder and uterus. The question was one of differentiation—appendicitis versus salpingitis. It was viewed as the former, because the line of extension was upward and outward toward the line of the mesentery, and not toward the line of the round ligament, as it would probably have been had it been salpingitis.

Dr. Cleveland said he always bore in mind the possibility of appendicular inflammation in connection with pelvic disease in women. Several times he had found a diseased appendix attached to the ovary and tube on the right side, and in one instance to a suppurating left ovary. Several times, in removing the uterus by vaginal hysterectomy, he had found the appendix presenting through the opening, and a few years ago he had removed an appendix four inches long through such an opening. The speaker said it seemed to him that the appendix could be found almost anywhere in the body.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, December 4, 1900.

Frederick Peterson, M.D., President.

The Terminal Condition in a Case of Diplegia.—Dr. William M. Leszynsky presented a man twenty-one years of age, in whom the chief feature of interest was a trembling of the hands, which had existed as long as he could remember. Nothing was known of his early history except that he had always been nervous. His mother had died of cancer of the uterus. The trembling had always been more marked on the left side, and his condition was apparently growing steadily worse. On careful examination no disturbance of sensibility could be detected. There were excellent muscular development on the left side and a spinal curvature, probably arising from the use of one side more than the other. There were no signs of atrophy. There was some asymmetry of the cranium. There was no disturbance of vision, but concentric contraction of the visual field. There was no nystagmus, and the pupils and fundi were normal. There was a positive tremor when at rest, and a more active tremor on motion. He held the left arm in extension, but close scrutiny showed that all of the rigidity was in the extensors. The elbow jerk was elicited only on the right side. Both knee jerks were exaggerated. Ankle clonus had been demonstrated on both sides, though it was much more marked on the left. Dr. Leszynsky said that this man had probably recovered from a paralysis that he had had at one time, and was now suffering from a terminal condition of an infantile palsy. Undoubtedly there was a good deal of functional disturbance added to the organic trouble.

Dr. M. Allen Starr thought the case was an athetosis on the left side, and that probably the same lesion, to a minor degree, was present on the opposite side. It was apparently a post-diplegic condition.

Dr. B. Onuf called attention to the lordosis and the unusual muscular development of the deltoids.

Dr. E. D. Fisher also looked upon the case as one of cerebral diplegia, more marked on the left side, and with the athetoid movements often seen in such cases. This extreme muscular development seemed to him not at all uncommon in this class of cases. He would like to know concerning the electrical reactions.

Dr. B. Sachs said that there could be no doubt that the left side was the centre of disturbance, and it was also probable that a part of the tremor was functional. The condition of the muscles in the scapular region seemed to him fully accounted by the spinal curvature present.

Dr. F. Peterson agreed with the diagnosis of post-paralytic athetoid form of movement. When the paralysis was small he thought these finer movements were more apt to be present.

Dr. Leszynsky regarded the remarks of Dr. Sachs a sufficient answer to those of Dr. Onuf. He had not yet tested the electrical reactions. It seemed to him that this man could be benefited if properly trained. Hypnotism had been suggested, and it seemed to him worthy of trial. The method used for ataxics would probably prove beneficial; it had just been commenced.

Report of Two Cases of Spinal Tumor with Operation and Removal.—Dr. M. Allen Starr said that five years ago he had been able to collect one hundred and forty-five cases of spinal tumor, in twenty-two of which operation had been undertaken. In the cases forming the subject of the present paper, the symptom pain had been very prominent, and this, together with the symptoms of pressure on the cord, had allowed of the diagnosis being made.

Case I.—Mrs. E. W——, thirty-five years of age, had been in good health previous to March, 1899, at which time she had begun to suffer from paroxysms of pain near the heart at night. They were not brought on by exertion, but were much increased by touching a region to the left of the nipple. From September, 1899, to May, 1900, she had been treated by many physicians for angina pectoris, hysteria, and other disorders. Nitroglycerin had always intensified the pain. On May 10th Dr. Theodore Janeway had examined her and found her in an extremely nervous condition and suffering from constant pain. The left knee jerk was exaggerated. Over the left side of the dorsal spine was extreme sensitiveness from the first to the eighth dorsal vertebra, and over the corresponding intercostal nerves at the angles of the ribs. There was no affection of the arms, and the internal organs were normal. When examined by Dr. Starr on October 26th she was suffering much from pain at the level of the fifth and sixth intercostal nerves, much more marked on the left side. There was very marked tenderness over the dorsal region from the first to the seventh dorsal vertebra. A condition of partial anæsthesia was found on the trunk and total anæsthesia in the legs. Her legs were quite powerless, but there was no atrophy of the muscles. Ankle clonus was present on both sides, and both limbs were cold, blue, and œdematous. She had recently been unable to control the sphincters. Dr. Janeway had made a diagnosis of tumor of the spinal cord at the fifth dorsal segment. On October 22d she had been operated upon by Dr. McCosh at the Presbyterian Hospital. On division of the dura an extremely œdematous state of the pia was observed, with one white plaque lying upon it. The cord was smaller and whiter than normal, and was not pulsating. No tumor was found. Three days later the wound was enlarged upward and the dura found to pulsate freely at the upper level, but not lower down. A tumor, one and one-eighth inches in length, lay upon the cord. It was oval, had a distinct capsule, and was removed *en masse* without difficulty. Subsequent examination showed it to be a fibroma. The cord had been reduced to about one-half of its diameter beneath the tumor. No attempt was made by Nature to heal the first operation wound, and in spite of great care an extensive bedsore developed over the hip. In the second week after operation the constricted feeling became less marked. The operation wound healed very slowly. In the fourth week after the operation she had constant fever, probably because of the extensive bedsores. The spinal incision healed about this time, but she died a few days later. The autopsy showed a softened condition of the cord opposite the exit of the second dorsal nerve from the dura, and the fifth and fourth dorsal nerves could be traced into this area. Owing to the rudimentary condition of the spine of the third cervical vertebra, an error of one vertebra had been made in the count at the time of operation. The case seemed to emphasize the fact that there should be no delay in operating for spinal tumor after the diagnosis had been reached. In this case the delay had arisen from an effort to try the effect of antisyphilitic treatment, the husband being known to be syphilitic. Bedsores had developed before the operation, and had continued to extend in spite of it, and had eventually caused death from sepsis. Gumma of the spinal cord was quite rare; only twenty-six such cases had been found in a series of four hundred cases. The tumor had been found about two inches higher than had been anticipated. Reed's table had been used as a guide at the first operation, but, according to Bruns, the operation should be done two segments above the upper limit of pain. This advice was nearer the truth in the present case. The level of the pain was about eight inches lower than the level of the tumor; hence in operating for spinal tumor the level of the cord should be exposed at least four inches higher than the level of the spinal nerve in which pain was found.

Case II.—Mrs. K——, forty-six years of age, had been in good health until May, 1900, when after a slight injury she had been delivered of a dead child. Soon afterward she had begun to suffer pain over the left hip, and this pain had extended down to the left knee. It had caused insomnia and progressive loss of health. In September she had noted numbness of the left foot. On October 16th, on admission to the Presbyterian Hospital, she was pale and feeble, and seemed to be suffering from paroxysms of pain over the left trochanter and that side of the sacrum. There was a drop-foot due to paralysis of the peronei and anterior tibial muscles. The bladder required catheterization, and the rectum had to be emptied by enema. There was an area of anæsthesia down the back of the left thigh and leg, and a smaller area was found on the right side. Under mixed treatment the paralysis extended, and the pain became more severe. An area of tenderness to pressure was found over the second, third, and fourth lumbar vertebræ, and pressure here aggravated the pain in the hip. It seemed probable from these facts that there was a tumor pressing on the cauda equina, and extending as high as the level of the exit of the second lumbar nerve. The functions of the sacral nerves and last lumbar nerve were evidently affected on the left side. A diagnosis of a cauda lesion was reached because of the level of the pain. On November 15th Dr. McCosh removed the spines and arches of the second, third, and fourth lumbar vertebræ. Dissection showed a tumor involving both the soft and hard tissues of this region. The spines and arches had been eroded by the tumor, which subsequently proved to be an endothelioma. This tumor had invaded the spinal canal and produced pressure on the dura. The patient was in a critical condition for two days after operation, but then had improved rapidly, and had had no pain since the operation. A considerable degree of atrophy had developed in both peronei. The wound had healed perfectly, and there was no evidence of recurrence. It was reasonable to hope for recovery unless there should be speedy recurrence. Out of one hundred and forty-five cases of spinal tumor that he had collected, the history had been fairly clear in one hundred and twenty-two. In seventy-six cases an operation should have been feasible, and, according to the pathological report, in seventy-five per cent. the tumors could have been removed.

Dr. A. J. McCosh said that he had found spinal surgery much more satisfactory than brain surgery; certainly the localization of the lesions had been more satisfactory. It was difficult to say, however, that a lesion was situated at any one segment of the spinal cord; but, as a portion of the cord equal to three or

four vertebræ must be exposed, a slight error in localization was not of great importance. He had had recently a case presenting symptoms almost exactly like those of the first case reported in the paper. The line of anæsthesia had been almost the same, but there had been no paralysis of the arms. The autopsy showed a crushing injury of the cord between the fourth and sixth cervical vertebræ. The ordinary rules laid down had indicated a lesion much lower down, and he had in this way been misled at the operation. He had not, as a rule, found laminectomy a very serious operation, most of the patients having exhibited comparatively little shock; hence, one should not hesitate in advising the operation when the diagnosis was sufficiently clear. He agreed thoroughly with what Dr. Starr had said about the inadvisability of delaying the operation for weeks in order to give antisyphilitic treatment a trial. He had met with a number of cases in which he believed the fatal result was attributable to such delay. When bedsores were already present the case was practically hopeless, the patient almost invariably dying from sepsis. It was well to remember that tumors of the cord were usually found higher up than at the estimated level. By beginning above and working downward, it seemed to him that the healing-process would be favored. He was not of the opinion that there was any good ground for believing that the operation of laminectomy so weakened the spine as to lead to disability. Mention was made of one of his cases in which a man was engaged at an occupation requiring the frequent lifting of heavy weights, yet he had felt no inconvenience as a result of the operation upon his spinal column.

Dr. Pearce Bailey reported the case of a man forty-one years of age, who had been treated for some time previously for a variety of troubles. When seen in May he had stated that about fifteen months previously he had begun to have intense pain on the inner side of the left thigh. There had been an interval of a few months in which this pain had almost subsided. There was slight atrophy in the left leg; the left knee jerk was absent; there was very slight anæsthesia. The case was diagnosticated as one of tumor of the cauda equina. Dr. McCosh had operated upon him on the 22d of May. He had removed the last dorsal and the first and second lumbar vertebræ, and had exposed what had looked at first like a blood clot, but microscopical examination had proved this to be a round-cell sarcoma. Although it was probable that all of this sarcoma had not been removed, the man had done extremely well all these months, was free from pain, and had resumed his occupation.

Dr. Sachs agreed with those who had advised against delaying in these cases in order to try specific treatment. He was thoroughly in favor of operating just as soon as the diagnosis had been established with reasonable clearness. It was a great mistake, in his opinion, to look upon operation as a *dernier ressort*. Gumma of the cord was quite rare, and even in these cases very little had been accomplished by the administration of the iodides; hence, such treatment might very well be neglected. In one of his cases, in which the operation had been done quite early, the man had been restored promptly to health. In another case he had not been allowed to operate early, and the recovery had been far from satisfactory. It seemed to him that a little too much importance was attached to the mere matter of localization; the important question was in regard to the nature of the morbid process and whether or not a tumor was present. In Pott's disease the sensory disturbances were sometimes as marked as when there was a tumor of the cord. Pain was the important symptom, but this was applicable more particularly to dorsal rather than to ventral tumors. He was not prepared to speak regarding the relative frequency of these two forms of tumor. He was of the opinion that a very extensive laminectomy could be done without causing notable disability or deformity. Early operation, he felt sure, would make spinal surgery much more satisfactory than brain surgery.

Dr. Theodore C. Janeway said that he regretted very much that in his case the diagnosis of spinal tumor had not been made sooner. There had been pain a year previously, but the pain had disappeared for a considerable time, and when he had first seen the patient she had been so extremely nervous that the question of hysteria had been seriously considered at first. The case had progressed very rapidly during the part of the summer in which he had not seen her.

An Analysis of the Symptoms Observed in Cases of Tuberculous Meningitis at the Babies' Hospital.—Dr. C. A. Herter read a paper with this title. There were 24 cases of tuberculous meningitis, and in 15 of these there were autopsies. In these 15 cases, 6 were at the age of eight months; 7 patients were one year old or under. In 9 cases of tuberculous meningitis without autopsy, 6 patients were five months old. These figures showed that tuberculous meningitis was not so rare in the first year of life as had been supposed by some writers. Nineteen of the cases had run their course in less than one month. The fontanelle had been markedly distended in 7 of the 24 cases, and in 3 there had been a marked excess of fluid found at autopsy. In 1 case the fontanelle had been depressed—a patient sick for four or five months. In 6 cases there had been a delay in the closure of the fontanelle. Vomiting had been noted in 19 of the 24 cases, and had been the first symptom in 14 cases. In 5, in which there was no vomiting, the autopsy showed nothing different from the cases that had presented vomiting. In 11 cases there had been marked constipation. In cases coming to autopsy there had also been tuberculous lesions in the intestine. In several of the cases there were tuberculous ulcers of the colon, and yet constipation instead of diarrhœa had been present. The pupils were unequal in 12 of the 24 cases, and dilated in the others. The pupils were contracted in only 2 cases. Nystagmus was observed in 4 cases, and strabismus in 10 cases. In the cases showing strabismus there were marked lesions at the base and in the interpeduncular space. There were general convulsions in fifty per cent. There was no case which did not present either rigidity or convulsions. In cases without meningitis, but with tubercles in the brain, convulsions were not so common. Paralysis was noted in 10 of the 24 cases of tuberculous meningitis, and was monoplegic in a number. The variability of these palsies was a rather notable feature. In the cases without meningitis, but with tubercles in the brain, no palsies or paralyses were noted. The tache cérébrale was noted in 7 cases and flushing of the face in 10 cases. All the cases of tuberculous meningitis with autopsy had presented stupor or coma, or more or less irregularity of respiration, while these had not been observed in any of the cases with tubercles but without meningitis. Hyperæsthesia had been noted in only 1 case, and in only 1 had there been a well-developed cephalic cry. Retraction of the abdomen had been noted to a greater or less degree in 15 of the cases of tuberculous meningitis, but not at all in the other cases. The fever had not been high in the uncomplicated cases, and the pulse had shown nothing distinctive. In the cases without meningitis marked opisthotonos and convulsions had been the rule, and early vomiting had been much less frequent than when meningitis was present. Only 2 or 3 of the cases had presented solitary tubercles. In all of the autopsy cases the cerebral tuberculosis had been clearly secondary. The intestine was the seat of

tuberculous lesions in 11 of the 13 cases in which the intestine was examined. The knee jerks were increased in a large proportion of cases, and absent in only 2. An interesting feature was that at times the knee jerks would be alternately exaggerated and absent.

Dr. Leszynsky said that he had made some observations in children under three years old with regard to the knee jerk, and had noted that in the early stages the knee jerks had seemed to be absent, but as soon as the pressure symptoms appeared the knee jerks became exaggerated and remained so until death.

Dr. Sachs said that the diagnosis of tuberculous meningitis was usually delayed by the general practitioner because he overlooked, as a rule, the cranial nerve symptoms so commonly found quite early in these cases, and waited for some of the more common and typical symptoms. He would like to know whether examination of the fundus and lumbar puncture had been of any diagnostic aid.

Dr. Herter replied that lumbar puncture had been practised in a few instances, and in two or three tubercle bacilli had been found. The examination of the fundus had been undertaken in so few cases that no deductions could be made. None of the cases diagnosticated as tuberculous meningitis had ended in recovery.

Dr. Sachs said that in a series of cases of sporadic meningitis lumbar puncture had been made, and the diplococcus had been found in almost every instance. He had been surprised also at the large number of recoveries in these cases of sporadic meningitis in which the diplococcus had been found. Their clinical course had been greatly at variance with the older descriptions of cerebro-spinal meningitis. The onset had been very violent, the fever lasting often a week or more, and then recovery was rapid.

Dr. Herter said that in the cases he had seen there had been a much more violent onset than in tuberculous meningitis.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, December 21, 1900.

Charles N. Dowd, M.D., Vice-President, in the Chair.

The Present Status of the Treatment of Puerperal Infection.—Dr. Henry J. Garrigues read a paper with this title. He said that in 1883 he had presented to this society the results of the then new treatment of puerperal patients. From 1875 to 1883 3,504 deliveries had occurred with 146 maternal deaths, or a mortality of 4.17 per cent. During the first three months after the change of the treatment at the Maternity Hospital there had been 102 confinements without a single death, a freedom from mortality that at that time had seemed almost miraculous, but which soon had become quite a common event. During the first nine years of the new era there had been 3,879 deliveries with 33 deaths, of which only 7 had been due to sepsis, or a total mortality of 0.87, and a mortality from sepsis of 0.18 per cent. At the present time the total mortality in lying-in institutions was about 0.5 per cent. While our public institutions all followed the rules of aseptic and antiseptic midwifery, these rules were far from being observed in private practice in this country. He did not ask for asepticism in private practice, for it seemed to him impracticable, but it was the duty of every obstetrician to practise antiseptic midwifery. In the present paper he would use the word infection in a very broad sense, including not only the disturbances resulting from microbic invasion but also the intoxication resulting from the absorption of the toxins produced by the microbes. Puerperal infection was a wound infection, and hence it might be either trifling or severe. As the diseased conditions varied greatly, the treatmen must also vary considerably.

Injections.—Intra-uterine injections demanded a certain amount of skill not found in every legally qualified practitioner of medicine. If corrosive sublimate were used there was danger of acute poisoning. Some years ago he had collected twenty-three cases of death attributable to the use of corrosive sublimate. Shortly after an injection as many bacteria had been proved by bacteriological examination to be present as before the injection. He had seen cases in which each intra-uterine injection had caused a rise of temperature, and the patients had recovered after these injections had been stopped. At the beginning, however, an intra-uterine injection after a curettage was useful.

Cauterization.—When the wounds became diphtheritic he was accustomed to apply a caustic composed of equal parts of chloride of zinc and distilled water. Vaginal injections should be given once in three hours and once daily the parts should be inspected with a speculum, and if the diphtheritic process had extended the cauterization should be repeated. The object of this cauterization was to kill the microbes on the surface and also to seal the channels leading into the interior of the tissues. He had found chloride of zinc better than other applications commonly employed.

Aperient Enemata.—At the beginning of puerperal infection the bowels should be thoroughly cleared out. When there was peritonitis he did not move the bowels except by occasional enemata. Large enemas of soapsuds with ox gall were useful.

Anodynes.—As pain was not only unpleasant but weakening, it was important to conquer it. This was done by the local and internal use of opiates. To reduce the temperature the local application of cold was the best means. Ice coils were convenient for this purpose, but baths and packs were sometimes desirable. If the interior of the uterus were infected it was his custom to leave a suppository containing gr. c. of iodoform in the cavity, and to renew it from day to day. Iodoform gauze was good for packing but not for drainage. If the uterus had not properly contracted, ergot by the mouth or faradization of the uterus was indicated.

Internal Antiseptics.—If the patient had been exposed to diphtheria she should be given diphtheria antitoxin. Antistreptococcus serum had apparently been proved not only useless but harmful. Unguentum Credé, an ointment containing soluble silver, had been extolled in this city because of its supposed efficacy in a single case, but he had not personally seen any benefit from its use; however, it was at least harmless. The attempt had been made to establish an artificial leucocytosis by the administration of nuclein. It was apt to cause pain in the bones, especially in the tibia, but this passed off in a week. A rational and useful modern method of combating sepsis was by washing out the whole system by the injection into the veins or into the cellular tissue of one or two pints of saline solution at short intervals. Sometimes vomiting was such a prominent feature as to demand attention. The administration of cocaine or of hydrocyanic acid, or the application of an ice coil to the epigastrium, had proved most useful in his hands. Years ago he had presented a paper in which he had reported the treatment of thirteen cases of diffuse peritonitis by the opium treatment. Seven of these patients had recovered, which was probably as good a result as could be expected.

Curettage.—If there was any doubt about the placenta having been totally removed, the patient should be anæsthetized, placed on a table in the dorsal position, with the knees well flexed and supported in a leg-holder. A systematic digital exploration of the uterine cavity should be made, special attention being paid to the horns of the uterus. Any remaining portions of the secundines should be scraped away with the finger nails. This was far better than using instruments. He did not think he had ever seen a patient recover when curettage had been resorted to after sepsis had become well established. By scraping the inside of the uterus one broke down the protecting wall by which nature limited the disease, and so carried the pathogenic germs directly into the lymphatics and capillaries. On the other hand, he had found the curette a wellnigh indispensable instrument in cases of abortion.

Abscesses.—When an abscess pointed above Poupart's ligament, a large incision should be made parallel to this ligament. Then the finger should be introduced, and, if deemed necessary, through drainage established by way of the vagina. If an abscess could be reached easily through the vagina it was better to make a transverse incision behind the cervix and open the abscess. If the latter were situated in the broad ligament it could be opened without entering the peritoneal cavity.

Laparotomy.—Whoever had seen an autopsy on a person dead of diffuse peritonitis must feel timid about opening the abdominal cavity during life. It had been done, but the results did not seem to be better than the older treatment. Since the uterus was in most cases the starting-point of infection, gynæcologists had been inclined to remove that organ, but to be of service this operation must be done before the microbes had invaded the general system. It was difficult to determine this fact, and hence the operation was liable to be done either too early or too late. He had attempted hysterectomy only twice in such cases. In the first he had operated a few days after confinement, but had been compelled to desist from operating to avoid a death on the table. In the other case he had operated about three weeks after confinement, and while the operation had done no special harm, the patient had succumbed later to pleurisy. He was inclined to think that surgical interference, inclusive of intra-uterine douches and curetting, had done more harm than good. In the hands of men of exceptional judgment and skill a few lives would be occasionally saved, but the average practitioner would best subserve the interests of his patients by abstaining from even such seemingly simple operations as intra-uterine injections and curettage.

An Exact Diagnosis Essential.—Dr. E. A. Ayers thought puerperal infection, being distinctly a surgical fever, should be treated like other wound infections, with only such modifications as were made necessary by the special organs involved. What was most needed at the present time was exactness of diagnosis. Certain forms of this infection extended with great rapidity; hence one must operate early if this step was to be effective, yet in doing so one was compelled to operate before an accurate diagnosis could be made. For this reason it seemed that exploratory incisions and hysterectomies were likely to cause more deaths than if they were not done. It was well known in hospital practice that only a very small percentage of cases terminated fatally, even though many appeared to be desperately ill, and hence it seemed unwise to advocate surgical interference. As soon as there was a rise of temperature no time should be lost in determining the cause of the fever. A knowledge of the history of the labor was most important here. If it was known that there had been a tedious labor and that the head of the child had pressed upon the soft parts in a certain place for hours, there was good ground for suspecting that a slough had formed. If it was known that the placenta had been removed completely the curette should not be employed. The retention of the membranes alone did not seem to him to call for such interference. He did not find it often necessary to go farther than local cauterization and local irrigation with sterile water.

Dr. Ralph Waldo said that he had been on the house staff of the New York Maternity Hospital at the time when Dr. Garrigues had done a good deal of his pioneer work in the field of antiseptic midwifery. As soon as a fetid discharge was detected he was accustomed to cleanse the vagina thoroughly, first with injections of corrosive sublimate, and afterward with sterile water. He then curetted the interior of the uterus, using a large dull curette, and completed the operation by irrigation of the cavity. Packing was used only in cases of hemorrhage. This was the treatment employed by him at the Lebanon Hospital, and not a single patient had died who had been septic on admission but not suffering from general sapræmia. At the present time antiseptic drugs were not administered by the mouth in these cases. Some cases were admitted with salpingitis or with inflammation affecting the tissues in the vicinity of the uterus. In such cases an ice bag was placed on the abdomen, and the case was kept under careful observation. As soon as pus could be detected and located the abscess was opened, usually under primary anæsthesia. All of the patients who had not entered the hospital with the abscess already opened had recovered. These abscess cavities were washed out and disinfected with peroxide of hydrogen, and the cavity was very lightly packed with gauze. Iodine had sometimes been found in the urine, and this had been asserted by some to be a positive indication of iodoform poisoning. This he did not believe, though it, of course, indicated that iodine was being eliminated by the kidneys. He was opposed to the internal use of iodine, carbolic acid, and similar preparations, as he considered them poisons, and liable to injure rather than to benefit the patient.

Hysterectomy Powerless in Acute Cases.—Dr. H. J. Boldt thoroughly approved of discarding the curette in favor of the finger. The use of the curette in these cases, he said, should be restricted to those who thoroughly understood it. He wished to assert boldly that no patient had ever recovered when hysterectomy had been done for actual puerperal septicæmia. This had never occurred; when such had been claimed it was to be explained only by a mistake in diagnosis. Septicæmia was due to invasion of streptococci into the general circulatory system, and rapid multiplication there. Every case of this kind that he had seen had ended in death, no matter what the treatment, and hysterectomy could only hasten the fatal issue. When there was a metrophlebitis, and from the area of infection in the uterus a stream of parasites was continually passing into the system, and other methods seemed to be futile, and if one were able to show by bacteriological examination of the blood that streptococci were present there, one might expect benefit from such a radical operation as hysterectomy, but only under these conditions. He knew of no method of treatment that would save the more acute cases. In his opinion, a deep-seated abscess in the parametria should be let alone until it pointed; one should not grope around in these parts.

Pyæmia.—Although the prognosis was very bad in the pyæmic cases, it was not absolutely hopeless when the pyæmia developed rather late. Patients presenting a general peritonitis due to a chronic septic infection, with no distinct encapsulation, were best treated

by making a free incision into the abdomen and washing out the cavity.

Dr. Henry C. Coe said that the first question arising in actual practice was as to whether the infection had extended beyond the uterus, yet this was a most difficult one to answer; hence our methods must be more or less vague. He was opposed to the use of the curette after the first or tentative exploration. These patients were more apt to be benefited by too little than too much treatment.

Dr. S. Marx said that from the trend of the discussion this evening it would seem that puerperal septicæmia could not be a very dangerous malady after all. It was now over a year since a case of true puerperal sepsis had developed in the New York Maternity Hospital. The treatment employed at that hospital now was practically that introduced by Dr. Garrigues in 1882, except that the vaginal injections were rarely given. He had not yet been able to fix the indications for hysterectomy in puerperal infection. He had seen iodoform poisoning produced by the introduction of a narrow strip of iodoform gauze into the uterus; hence he objected to Dr. Garrigues' practice of leaving iodoform suppositories. The woman referred to had become maniacal, and had had an extremely rapid pulse, all from the iodoform poisoning. After some days she had recovered.

Dr. Garrigues, in closing the discussion, said that he did not use the curette for the removal of membranes merely, but for taking away retained placenta; nevertheless, if a large piece of membrane were left behind immediately after delivery it should be removed. He was surprised that so much objection had been made to the use of iodoform, as Dr. Pryor, of this city, made it his special aim to saturate the system with iodine. In his personal experience he had never seen any intoxication from the use of the iodoform suppository or the iodoform gauze. According to the latest work of the best bacteriologists only four or five per cent. of cases of puerperal infection were lost when the infection was due to streptococci. Quite a number of cases had been reported in which the infection had been due to other bacilli, and particularly to the bacillus coli communis and the pneumococcus.

Clinical Data Relating to Ectopic Gestation.—Dr. Egbert H. Grandin read this paper. He said he had repeatedly recorded instances of ectopic gestation, and had called attention to the fact that rarely had the classic symptoms described in most text-books been present, and yet there had been sufficient to arouse the suspicion of the thoughtful and careful practitioner. In his experience, based on about fifty cases, it had usually been by exclusion that he had made the diagnosis. He had repeatedly operated upon women who had given no history of amenorrhœa followed by irregular bleeding. These women had usually given a history of the last menstrual flow having been markedly less than usual. This was a point which deserved to be kept in mind. Again, ectopic gestation might exist without associated uterine enlargement, and without enlargement of the lower uterine segment—the so-called Hegar's sign of early uterine pregnancy. As a rule, he had found colicky pains fairly constant as a symptom of ectopic gestation, yet he had met with it in other cases. Five cases were cited to justify the concluding statement of the paper, that an exploratory vaginal section was of very great value. It should be done in every case in which the clinical history in the least suggested the possibility of ectopic gestation. If carried out by experienced hands it was practically devoid of risk. When precedent amenorrhœa was followed by bleeding, one could be sure that the pregnancy was not normal. If under anæsthesia examination showed an enlarged and congested tube the indication for operation was stringent.

Dr. Simon Marx said that the correct diagnosis of extra-uterine pregnancy would be made much oftener if physicians would only keep constantly in mind the possibility of its existence. He could not recall having operated upon a case that had simulated ectopic gestation in which he had regretted such interference. When an extra-uterine tumor was present, together with symptoms of pregnancy, and yet the uterus did not present the size and shape which it should have in an ordinary uterine pregnancy at this stage, one might be reasonably sure that the case was one of extra-uterine pregnancy.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 20, 1900.

William H. Katzenbach, M.D., Vice-President, in the Chair.

Municipal Hospital for Consumptives. — Dr. A. Jacobi presented the following resolutions on behalf of a committee of the council, and they were unanimously adopted by the Academy:

"*Resolved*, That the committee appointed by the Academy be instructed to use its influence to have the municipal hospital constructed for cases in the early, and presumably curable, stage of phthisis;

"*Resolved*, That while the proper designation for such a hospital would be 'for curable cases,' yet in view of the bad effect the refusal to be admitted would produce, the designation should be 'Hospital for Incipient Cases';

"*Resolved*, That the committee be instructed to use its influence to have the hospital placed in that locality which will be the most productive of good, and where there shall be such space that it will not be an injury to the neighborhood, which would be the case if it were placed in a populous locality;

"*Resolved*, That the committee be instructed to use its utmost endeavors to have such examinations for admission made by thoroughly competent physicians possessed of such moral stamina as shall prevent advanced and incurable cases from being sent to the hospital for incipient cases;

"*Resolved*, That the committee be instructed to use its influence to have the rules and regulations of this hospital such that it shall not become an unnecessary burden upon the community."

Remarks on Enteroptosis.—Dr. Max Einhorn read a paper on this subject, introducing it by the presentation of a patient having this disorder. He said that enteroptosis had been known since 1885. The term gastroptosis laid too much stress upon the stomach; hence, the word enteroptosis was better, as it meant a tendency to a descent of the abdominal organs generally. The corset seemed to be an important factor in the causation, but it was not the only cause. Enteroptosis was occasionally found in very young women who had never worn corsets, and it had also been observed in men. According to some observers, enteroptosis was largely dependent upon a congenital weakness of the tissues. A weakened condition of the abdominal walls appeared to be the primary and most important factor in the etiology. This led to a diminished tension within the abdominal cavity, and to a disturbance of equilibrium. The constriction of the corset led to atrophy of the abdominal wall, thus still further increasing this weakness. The occurrence of either enteroptosis or of movable kidney could be detected only by clinicians well versed in the physical examination of the abdomen.

Both enteroptosis and movable kidney seemed to be much more frequent among women—indeed, he had found it about ten times more frequent in the female sex. In most instances morbid manifestations were encountered. The patient often complained of a faint feeling or of weakness after rising. A feeling of weight was occasionally experienced in the lower portion of the abdominal cavity, and a dragging sensation in the epigastrium. Moreover, disease of the digestive tract complicating enteroptosis proved unusually rebellious to the ordinary treatment. Cases of enteroptosis lasting for a long period were apt to lead to anæmia. As a rule, these patients were thin and appeared younger than they really were. Palpation was extremely easy of performance, there being, as a rule, no rigidity of the muscles. In the standing position the epigastric region appeared depressed, while the lower part of the abdomen was bulging. The stomach occupied an abnormally low position, as could be easily demonstrated by the splashing sound. On tapping on the left side of the abdomen below the ribs, the stomach being partly filled, a splashing sound would be elicited, and its situation would indicate the position of the stomach. The transverse colon, the cæcum, the descending colon, and the sigmoid flexure could often be palpated. In these cases the right kidney would often be found movable. This was best detected by bimanual palpation. If the physician, standing behind the patient, by encircling the abdomen with both hands and pressing upward, gave relief to the patient, there was reason to believe that enteroptosis was present. The prognosis of enteroptosis was good. A perfect cure was certainly possible; he had himself had at least half a dozen such cases. Even though the organs did not return to their normal position, the subjective symptoms could be quickly relieved. The treatment consisted chiefly in the application of a properly fitting abdominal bandage, together with massage and improvement of nutrition. The bandage should support and lift up the lower part of the abdomen. Special pads for movable kidney seemed to him useless. It was quite essential that the bandage should be kept from slipping upward by bands passing around the thighs. In women having very prominent hips it might be necessary to cut out "windows" in the bandage. It was also exceedingly important that these patients should have sufficient exercise, and should be well nourished. Out-door sports were specially suitable for them, and massage was useful in the milder cases. The patient should be given plenty of good nourishing food, being directed to take bread and milk between meals. Iron and arsenic were often indicated, and the bromides when there was great nervousness. Laxatives were sometimes required, but should be used with caution and judgment.

Nervous Dyspepsia and Enteroptosis Related.—Dr. A. Rose agreed with the reader of the paper that enteroptosis could be cured in many instances. His own plan of treatment was to strap the stomach with strips of adhesive plaster. The idea had suggested itself to him from the knowledge that the strapping of the thorax in cases of fracture of the ribs was very serviceable and was well borne. He preferred adhesive plaster to the bandage in these cases because the patients were thin, and it was difficult to fit a bandage and keep it snugly applied. Comparatively few of his patients had complained of irritation of the skin, and when they had done so he had found that this could be overcome by the application of Unna's zinc plaster before putting on the adhesive plaster. He had also tried a glue made by Unna out of oxide of zinc, gelatin, and glycerin, and so far as he had used it it had answered the purpose quite well. His own experience had led him to think that nervous dyspepsia and enteroptosis were closely allied. It was remarkable how quickly the nervous dyspepsia could be relieved by treatment directed to the cure of the enteroptosis.

Dr. Mary Putnam Jacobi said that no mention had been made of supporting the perineum at the same time the abdomen was supported. This principle was embodied in the Banning brace, and it seemed to her a useful one. It had been asserted by some that much nervous dyspepsia was dependent upon a hysterical anæsthesia of the mucosa of the stomach, and an associated perversion of the secretions. She was disposed to think that many needless operations were done for movable kidney. Many of these cases could be completely relieved without operation by improving the general nutrition and increasing the quantity of fat around the kidney.

Dr. H. W. Berg said that to establish the diagnosis of movable kidney there should be not only a movable mass in the region of the kidney, but it should have the shape of the kidney. This should be insisted upon in order to differentiate movable gall bladders and various tumors with long pedicles.

Dr. Einhorn said that it could not be denied that many cases of enteroptosis showed digestive derangements of a neurotic type, and that by treating the enteroptosis a cure would be effected more speedily than if the digestive disturbance alone were treated. Although he had seen seven or eight hundred cases of movable kidney, he had not yet seen one in which it had seemed to him an operation was necessary. All the symptoms that had been ascribed to movable kidney could be ameliorated or cured by other means. In about ninety-five per cent. of these cases it was possible to effect a practical cure without operation. It was obvious in cases of enteroptosis that little or nothing could be accomplished by simply fixing the kidney. By the same line of reasoning operations should be done for fixing the liver, the stomach, and other organs. He had known some patients to be relieved by the application of the bandage though they had not complained of a dragging sensation.

Officers Elected.—*President*, Dr. Robert F. Weir; *Vice-President*, Dr. C. L. Dana; *Recording Secretary*, Dr. John H. Huddleston; *Corresponding Secretary*, Dr. Louis Faugères Bishop; *Trustee*, Dr. Alexander A. Smith; *Member of Committee on Admissions*, Dr. John V. D. Young; *Member of Committee on Library*, Dr. C. L. Gibson.

Constipation Fever.—G. Edlefsen regards this as a separate pathological entity and has seen forty-nine typical cases. The disease consists in a temperature rise which is often very considerable, depending solely on the retention of fecal masses in the large intestine. This causative relationship is to be demonstrated by the absence of any other reason for the febrile movement and the fact that evacuation of the bowel is followed by a return to normal. The direct agency at work appears to be the passing of pyretogenetic substances, that is, toxins the result of decomposition, from the intestine into the blood. In most cases the pyrexia is of short duration, sometimes lasting not longer than a day, but usually the administration of purgatives and enemata is followed by a drop extending over a day or two before the normal is reached again. Frequently the disease is ushered in by severe colicky pains, the temperature rising suddenly and rapidly, with chilliness or even slight chills. The pulse does not follow the temperature; a true retardation being the rule and affording a valuable diagnostic sign. The therapy is obvious from the etiology.—*Klinisch-therapeutische Wochenschrift*, November 18, 1900.

Medical Items.

Growth of Population in Germany.—The growth of Germany since the war with France is the most remarkable phenomenon of modern Europe. Since the treaty of peace was signed in 1871 Germany has not extended her territory by a single acre on the Continent of Europe (if we except the acquisition of Heligoland), but she has increased her population by 16,000,000. The Germans numbered 40,000,000 in 1871; they number 56,000,000 now, and yet, although there are so many mouths to feed, the Germans are better fed, better clothed, and in every way more prosperous than they were then. This is attributed largely to the fact that for twenty years Germany devoted herself to improving the elementary education of her people.—*Tit-Bits.*

Antitoxic Qualities of the Bile of a Victim of Tetanus.—Vincenzi (*Münch. med. Wochenschr.*, September 12, 1899) studied the bile of a fatal case of tetanus. He had previously examined the blood of a patient who had survived an attack of the disease, but was unable to recover a trace of antitoxin therefrom. He administered the usual fatal dose of tetanus virus to guinea-pigs, and found that the bile of the human patient, when injected later, was able to prevent the development of the disease. When bile and tetanus virus were mixed and injected into a guinea-pig, a mild attack of tetanus resulted. The author's extended studies upon the subject appear to show that the bile in this case was free from the tetanus poison, and that it possessed distinct antitoxic qualities.

Journal Devoted to Seasickness.—The *New York Herald* of December 9th, says: "It will interest transatlantic voyagers to know that a journal has just been started in Paris, the object of which is to discover, if possible, some effectual means of preventing that bugbear of ocean travel, seasickness. This periodical, which is entitled *Le Journal de Mal-de-Mer*, is edited by Dr. Madeuf, who is president of one medical society, and an associate of several others. His aim is to form a league, which shall be composed not only of all persons who suffer from seasickness, but also of all steamship companies, hotel keepers, theatrical managers, and any other persons or places whose business is at present periodically injured in some way or other through mal-de-mer. Dr. Madeuf invites all sufferers from this malady to write to him, explaining the manner in which they are affected, and describing the various remedies which they have used. In the first number of the journal there are thirty-five leading questions and several minor ones on these two subjects which subscribers are requested to answer. Furthermore, Dr. Madeuf informs his readers that he intends to collect all obtainable documents, especially those of historical and scientific value, in regard to seasickness, and that he hopes to be able to formulate a plan by which adequate prizes may be offered to those steamship companies which succeed in constructing their vessels so that passengers on them will be quite as comfortable and as free from this annoying malady as they would be on land, as well as to those inventors who may succeed in discovering infallible remedies for mal-de-mer."

Thomas Sydenham.—Dr. J. F. Payne, who undertook the task of writing the life of the father of English medicine in the masters of medicine series, has just completed and published his book. It presents a vivid and lucid picture of the great man. From a review of the work in *The Lancet*, we gather that Thomas Sydenham was baptized on September 10, 1624, and died on December 29, 1689. He came of an old Dorsetshire family, being the fifth son of William and Mary Sydenham, of Wynford Eagle, a hamlet lying about eight miles from Dorchester. From the beginning of the Civil War the father and his sons fought against the king, and in the summer of 1644 Mrs. Sydenham, the mother, was killed by Royalist soldiers. In the following February, Francis was a major in the Parliamentary forces in Dorsetshire and afterward of sufficient importance to be specially exempted from the Act of Indemnity passed when Charles II. came to his own again. Thomas bore arms under his brother in the campaign in the West, and again in 1651, when he was a captain of horse and rendered important services to the Council of State, though, fortunately perhaps, he was absent from England at the time of the Restoration. In the Scotch campaign John, another brother, was killed, and Thomas petitioned the Protector for the arrears of his brother's pay. At Cromwell's special desire £600 (3,000) were ordered to be paid to Sydenham out of certain money belonging to the commonwealth in the hands of the commissioners, for coal dues in the port of Newcastle. Sydenham received incomplete education at Oxford, first at Magdalen Hall and then at Wadham. He was created a Bachelor of Physic in the university on April 14, 1648, but it was not until 1663 that he obtained a license of practice from the Royal College of Physicians of London. The great plague of 1665, by enforcing a holiday, led Sydenham to write his first book, a small octavo of one hundred and fifty-six pages. It was a treatise on fevers, the outcome of his own observations. Several shorter contributions followed from time to time, though Sydenham was not fond of writing, and ill-health and want of leisure made composition difficult to him. From these shorter writings comes his classical account of gout, to which he was a martyr for many years, and we learn that he gave steel filings as a chalybeate, and introduced a fluid laudanum—still known as Sydenham's laudanum and analogous to the wine of opium. While Dr. Payne gives Sydenham every credit for the great advances he made in the study of medicine, he is quite impartial and shows the points wherein he was ignorant. He failed entirely to perceive the importance of anatomy and physiology. . . . It was the especial merit of Sydenham to proclaim the great truth that science was and always must be incomplete, and that danger lurks in the natural tendency to act upon it as if it were complete. Dr. Payne, therefore, well says that, while Harvey was the master of science, Sydenham was the master of practice.

The Percentage of Microbes in London Water.—According to the testimony of Sir William Crookes, F.R.S., the bacteriological examination of four hundred and seventy samples of London water showed six per cent. to contain more than one hundred microbes per cubic centimetre. The percentage for the two or three previous months was two per cent. and the comparative impurity of the samples collected this month would probably be accounted for by the large increase of rainfall over that of the previous month. It is satisfactory to know, however, that a number of special daily examinations have failed to show the presence of any pathogenic microbes in a sample of filtered London water. It is unnecessary to insist upon the importance of the water supply of London being jealously watched and supervised, and it is to be hoped that the practice which now obtains of at once communicating with any water company supplying water containing more than a certain proportion of microorganisms, in order that they may be made aware of the fact that their filters are working defectively and require attention, produces in all cases the results de-

sired. The actual degree of danger to health indicated by the presence of non-pathogenic microbes in the water supply is a matter as to which considerable difference of opinion exists, but there can be no question that the actual effectual inspection of the water supply of London is one of the main factors which insures for this great city the healthy conditions its inhabitants enjoy.—*Medical Press.*

Coughing as a Fine Art.—In an article on tuberculosis, contributed to the annual report of the Maine State board of health by Dr. A. G. Young, he treats of the above subject and says: "There are reasons affecting both the patient and those associated with him why cough should be suppressed by the voluntary effort of the patient so far as is practicable. How far this is possible has often been noted with surprise by visitors to properly conducted sanatoriums for consumptives. At the dinner table or anywhere else where large numbers of patients are found together, hardly a cough is heard. Unnecessary coughing is bad for the patient; loud and open-mouthed coughing subjects other persons in the same room to the possibility of infection. When obliged to cough, the patient should do so as lightly as possible, and with lips closed as much as he can. Even when the cough is hard, experiments have shown that the diffusion of particles of infectious sputum into the air can be easily prevented by holding something before the mouth. The open hand will quite effectually arrest all particles, but the rule to keep the hand as clean and as free from infection as possible, forbids the use of the hand for this purpose. A suitable object is a paper napkin or a square of muslin, to be burned after it has been in use for a short time. Professor Leube of Würzburg has his patients, when confined to the house, keep upon their table in a suitable dish a bunch of cotton twice as large as the fist, to be held before the mouth while coughing. A handkerchief may be used for this purpose and for no other, but when so used it presents the same danger in a minor degree as when the handkerchief is used as a receptacle for the sputum."

Diagnostic Points of Impetigo Contagiosa Bullosa.—1. History of contagion or epidemic; other pustular conditions upon the patient, attendants, or those in close contact with the patient. 2. Location of eruption upon exposed parts and those parts accessible to auto-inoculation and scratching. 3. The acute progress of the disease. 4. Usually mild constitutional symptoms. 5. "Eccentric and peripheral extension of its primary lesion" (Elliot). 6. Auto-inoculability of lesions. 7. Other symptoms of impetigo may be found, as the "stuck on" crust, vesicles, circinate lesions. 8. Furunculosis, especially on the head, often associated. 9. Prompt reply to mild local antiseptic applications. 10. Smears from the bullæ show diplococci, cocci in short chains, and zöoglœa, neutrophile leucocytes, large lymphocytes (in infants especially), rarely red cells and only a few eosinophile cells. 11. The blood shows nothing unusual or interesting, except the absence of eosinophilia. The last two points, absence of an excess of eosinophile cells in the blood and the contents of the bullæ, are strong differential points between this disease and some other bullous affections, such as pemphigus and dermatitis herpetiformis.—Dr. Martin F. Engman, *St. Louis Medical Review*, November 10, 1900.

Some Problems Pertaining to Tuberculosis.—The results desired may be summed up as follows: (*a*) There should be less danger to the well in health resorts, and (*b*) better care for the afflicted who come to these resorts. To secure such ends the following points should be observed: (1) States possessing climatic advantages favorable to tuberculous persons should not quarantine against tuberculosis. Patients coming to these resorts should come early. (2) Each State blessed with the conditions producing a congenial climate for such persons should enact and enforce rigid sanitary and preventive measures against infection from tuberculosis. (3) The general public in all States should receive systematic instruction; it should be the purpose of all to ascertain the true sources of tuberculous infection, and our States and cities should formulate rational rules to prevent and overcome these sources of danger. (4) These rules for the public should become popularized through the daily press and public schools, and literature should be freely circulated by boards of health. (5) Rules should be formulated for the government of households in which some member is afflicted with tuberculosis, to guard against the infection of the well members. (6) Rules for the safe deposition of tuberculous secretions should be concisely formulated. (7) Precautions should be taken against infected foods; dairies should be carefully inspected and the tuberculin test periodically given to dairy cattle. (8) Rigid precautions should be taken in cities located in health resorts where tuberculous persons congregate. (9) The compulsory reporting of tuberculous cases should be demanded by boards of health, and apartments occupied by all persons thus reported should be periodically fumigated. (10) As far as possible, tuberculous persons should be prevented from congregating in thickly settled districts. Many persons would go to ranches, or less densely populated regions, but these are destitute of the real necessities which are important in the treatment of this disease.—Dr. A. Mansfield Holmes, *Denver Medical Times*, November.

Gastric Cancer.—1. Cancer is one of the most potent factors in the causation of death, with a tendency constantly to increase in frequency of occurrence. 2. Gastric cancer occurs in about one-fifth of all primary cases. 3. In gastric cancer the pyloric region is affected in sixty per cent. of the cases. 4. The treatment of gastric cancer directed toward a permanent cure is in the present state of our knowledge limited wholly to surgical methods. 5. As early total extirpation of malignant growths with the hope of permanent cure is the goal toward which we are constantly striving, and as these growths in gastric cancer occur at the pyloric region in sixty per cent. of the cases, it would seem to follow as a natural conclusion that pylorectomy would be the treatment most frequently prescribed for the cure of this malady. 6. Inasmuch as early diagnosis is the greatest requisite for directing proper radical treatment, the internist and the surgeon should turn their best efforts in this direction. 7. If the operation of pylorectomy were performed before obstructive symptoms manifest themselves and before the occurrence of metastasis, the immediate results would be as favorable as in any other abdominal work and the remote results as good as in extirpation of the breast for carcinoma.—Dr. J. E. Allaban, *Hot Springs Medical Journal*, October.

Penetrating Thoracic Wounds.—The rules of practice in penetrating thoracic wounds are comparatively simple and may be briefly stated as follows: 1st. In all penetrating chest wounds avoid exploration, disinfect the parietal wound, and immediately apply an occlusion dressing with partial immobilization of the chest. Put and keep the patient in the recumbent position; calm the circulation by quiet and if necessary by opiates. Watch closely the possible supervention of internal hemorrhage and infection. 2d. Intrapleural effusions of blood though considerable, if not threatening life, should not be evacuated too hastily. Time should be given for definite cessa-

tion of the hemorrhage, then it may during the second and third weeks be gradually removed by aseptic paracentesis. 3d. In cases of severe and progressive internal hemorrhage, its source, *i.e.*, whether parietal or pulmonic, should be settled. The former should always be controlled by forceps or ligature without opening the chest, and the latter, if progressive and causing dangerous anæmia, dyspnœa, and disturbed cardiac action, may demand a large plastic thoracotomy and suture or tamponade of the lung parenchyma. In a certain few stab wounds of the heart suture is practicable. 4th. However, in practice it is chiefly the advent of sepsis which requires surgical interference in these injuries. When either pleura or pericardium becomes distended with infected fluid, it should be promptly opened freely and drained, precisely as any other purulent pleurisy or pericarditis. —Dr. James H. Dunn, *The Railway Surgeon*, November 13th.

Leprosy in New York.—"Referring to your remarks in October *Clinic*, in which you quote me as saying there were one hundred lepers in New York, I will add that not only did I say that, but I have the private records of one hundred and thirty-nine cases." —Dr. Albert S. Ashmead, *The Southern Clinic*, December.

Leucocytosis.—Dr. L. H. Warner (*Medical Fortnightly*, December 10th) makes the following clinical pathological classification of the different leucocytoses: 1. Physiological leucocytosis which must be divided into: (*a*) a digestive leucocytosis; (*b*) a leucocytosis due to pregnancy; (*c*) a leucocytosis of the new-born. 2. Pathological leucocytosis which must be divided into: (*a*) a leucocytosis due to inflammation; (*b*) a leucocytosis caused by malignant tumors; (*c*) a post-hemorrhagic leucocytosis. 3. A leucocytosis influenced by medication.

Sepsis and Antisepsis.—Dr. James E. Davis (*International Journal of Surgery*, December) summarizes his paper as follows: (1) Inculcated principles of asepsis and antisepsis should precede the practice of the same. (2) A thorough mechanical cleansing with soap and hot water is the first and most important step toward asepsis. (3) The doctor of medicine should teach and demand the strict observance of cleanliness by assistants and associates. (4) Antiseptics must always be selected with due reference to their permeative power. (5) A detailed observance of asepsis should obtain in all medical work. (6) The most effectual and reliable agents for obtaining and preserving asepsis are boiling water, soap, alcohol, and bichloride of mercury.

Danger in Boiled Milk.—In the German *Milch-Zeitung* (No. 19) Herr Bernstein gives the following explanation of occasional noxious effects from boiled milk: (1) If milk is allowed to stand it turns sour with slight production of gas. (2) If it be pasteurized or heated to 70° C., and then allowed to stand, it shows cheesy masses, full of gas bubbles, and gives off the typical odor of putrefaction. (3) If it be boiled and then stands, the cheesy masses sink without gas formation to the bottom and a gradual solution of the albuminous substances occurs. In (1) the lactic-acid ferment predominates; in (2) this has been killed and gas-forming bacteria make their appearance; in (3) these are destroyed, and their place is taken by peptonizing microbes, the products of which may be occasionally poisonous. The writer recommends that when boiled milk is not immediately used some pure culture of the bacillus lactis, or what amounts to the same thing, a little stale, unboiled milk, should be added to it.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended December 28, 1900:

		Cases.	Deaths.
Smallpox—United States.			
Florida, Jacksonville	December 2d	1	
Kansas, Wichita	December 15th to 22d	10	
Kentucky, Lexington	December 22d	1

HERNIA OF THE URINARY BLADDER.

W. S. CHEESMAN, A.M., M.D.,
AUBURN, N. Y.

My interest in this subject was suddenly and acutely aroused by the following experience:

In the night of January 10, 1900, I was called to see in consultation a man aged sixty-seven years, suffering for eight hours from strangulated hernia. Ever since his twenty-fifth year he had had a left inguinal hernia which trusses failed to hold; hence it had grown and become scrotal. He possessed also a small umbilical hernia; and, in addition, a right inguinal hernia had recently developed. No more urinary trouble was observed than is usual with elderly men. The large mass on the left was irreducible by taxis, so I proceeded to operate.

A heavy, much hypertrophied sac was found containing a knuckle of dark gut. This was reduced, and the sac freed from its attachment to the spermatic cord and canal, in doing which a larger amount of fat than usual was observed, but not enough to deserve the designation of lipoma. The thick-walled sac was then lifted without traction, transfixed near its neck by a ligature carrier, the ligature (catgut) tied both ways, the sac cut away, and the rather large stump returned.

For some fortunate reason, I think mainly because of its hypertrophy, I was led to examine the sac after removal, and was disturbed to find attached firmly to it a disc of mucous membrane about as large as a silver dollar, and easily recognizable as bladder mucous membrane. The situation was cleared still further, when the bladder was disentangled from the ligature about the neck of the sac, and a finger passed into the viscus, urine thereupon welling out freely through a goodly opening.

The margins of the bladder wound were drawn out into the world by hæmostats, and closed with catgut carried through the muscle coat to, but not including, the mucous membrane. A second *étage* was then placed, inverting somewhat the first. The bladder was then returned within the abdomen, a drainage tube placed against the suture line in it, and the skin wound closed. The muscle and Poupart's ligament were, I regret to say, not united according to Bassini, as I feared leakage of urine within, which would necessitate reopening the outer wound.

A catheter tied in the bladder caused the patient so much annoyance that he pulled it out on the second day, after which urine was either drawn or passed voluntarily every two hours, and the bladder was washed out daily with boric-acid solution.

Primary union followed throughout. The hernia is at present apparently cured, and no urinary symptoms remain.

Examination of the excised sac showed that the bladder was virtually inseparable from it. It seemed probable that the weight of the hernia and sac had by traction on its peritoneal coat gradually drawn the corner of the bladder into the inguinal canal to the extent of over one inch. No pull was made while the sac was being tied; hence I do not consider the possibility of an artifact, or what has been termed "operative cystocele."

Any one interested in surgical matters must have read of the occasional presence of the bladder in a hernia, but how frequent an occurrence this is, and how rich is the literature of the topic, one does not realize till a research is made.

History.—The matter was first treated monographically by Verdier in a classical treatise published in 1769, and not again till Aue, in 1891, collected the cases recorded up to that year. Since then a number of articles have appeared, each endeavoring to bring the material up to date.[1]

There have been, besides, numerous clinical reports of cases with more or less extended review of the subject in German, French, Italian, and Russian. Little seems to have been made of the topic in English-speaking countries, however. The studies of Curtis (*Annals of Surg.*, June, 1895) and Gibson (Trans. Med. Soc. State of New York, 1897) being all of any importance that I can find. So, as the former appeared five, and the latter three, years ago, there seems a good excuse for recalling attention to a danger every surgeon should have in mind when operating for hernia.

Anatomical Varieties.—Three forms have been described: First, an extra-peritoneal, in which some portion of the bladder uncovered by peritoneum protrudes through the hernial opening, with or without a sac containing intestine; second, an intra-peritoneal, in which bladder covered by peritoneum enters the sac; and third, a mixed type (the "para-peritoneal" of Jaboulay and Villard), in which the bladder partly covered and partly uncovered by peritoneum protrudes. Writers differ as to the relative frequency of extra-peritoneal and mixed types, but all agree upon the great rarity of the intra-peritoneal form.

Etiology.—Bladder hernia is computed by Lotheissen to occur in about 3.2 per cent. of all cases of hernia, by Sjovall in one per cent. Nearly four times as many cases have been observed with inguinal as with femoral hernias. It is very rare under thirty, and increases in frequency after forty, probably owing to growth of the original hernia, increase of fat, relaxation of the abdominal wall, weakening of muscular tone of the bladder, etc. I have been able to find but six cases in children, viz., Pott's, aged thirteen (1770); Felizet's, aged twelve (1894), (doubtful); Kummer's, aged five (1892); Wyeth's, aged two and one-half (1895); Adams', aged eighteen months (1900); Foy's, operated upon in 1893 by O'Grady, aged six years, reported 1900.[2]

[1] Among the best of these are—Bourbon: Thèse de Paris, 1892; Siegel: Dissert., Würzburg, 1892; Maudry: Beiträge z. klin. Chir., 1893; Lejars: Rev. de Chir., 1893; Piquet: Thèse de Paris, 1893; Imbert: Ann. des Mal. des Org. Génito-Urin., 1896; Lotheissen: "Die inguin. Blasenbrüche." Beiträge z. klin. Chir., 1898; Brunner: Deutsch. Zeitsch. f. Chir., 1898; Sjovall: Inaug. Dissert., 1899; Ansinn: Inaug. Diss., 1899.

[2] So great is the rarity of bladder hernia in childhood, that a summary of these two latter cases reported during the last year may be of interest:

Adams' case (Clin. Rev., Chicago, 1900, vol. xii., p. 270). A

Among a number of causal factors suggested by different writers as productive of hernial cystocele, such as constipation, pregnancy, oblique position of the bladder, etc., none seems generally accepted except direct traction upon the bladder through its peritoneal coat, by the weight of the hernial sac and contents. Lotheissen accounts for the occurrence of extra-peritoneal hernias by assuming that the pre-vesical fat (lipocele) engages in the hernial opening, and drags the bladder after it. In Adams' unique case a bladder diverticulum closely adherent to the cord and canal constituted the sole hernial protrusion in an infant. It seems possible that here the testis in its descent may, in pushing before it the peritoneum, have carried down a portion of the attached urinary bladder, elongating and thinning it, till it assumed the finger-like form described.

Beyond doubt, during operations for radical cure, the bladder has been in many cases drawn out of the hernial opening by traction during ligation of the hernial sac. This is appropriately termed "operative cystocele" by Imbert. The great increase of cases observed during the last decade, since operations for radical cure of hernia have become common, gives added probability to this etiology.

I have been able to find records of one hundred and eighty cases of bladder hernia, which may be analyzed and tabulated as minutely as one wishes.[1] For practical purposes, however, the material divided itself largely and naturally into the following classes:[2]

1. Cases discovered at autopsy.[3] Beginning with that of Sala in 1520, twenty-two autopsy cases are recorded. In five instances the hernial bladder contained calculi. Verdier cites one in which five stones were found. A particularly interesting case which seems to have been overlooked by collectors, and which was the first described in America, was reported to the Medical Society of the County of New York on March 16, 1815, by James L. Phelps. The patient had the hernia fourteen years, the tumor slowly growing. With desire to urinate, the swelling in the groin became tense, and compression of this enabled the patient to start the stream. Finally, at the age of eighty, there was strangulation, not relieved by catheterization, taxis, or bleeding; and death followed on the third day. The autopsy showed the wall of the sac thickened, and containing, beside some sphacelated gut, a pouch five inches long, consisting of the anterior wall and fundus of the bladder.

2. Cases in which there were symptoms of vesical hernia.[1] There are thirty of these, and their study illustrates the rational and physical signs by which the bladder may make its presence in a hernia known, and put the surgeon on his guard lest he add another to the long list in which the bladder has been injured. These symptoms consist in various disturbances of urination; pain and tenesmus being the mildest and least suggestive, especially in old men. An increase of dysuria, with enlargement of the tumor in the groin, as in Ribell's case, would be a more pointed hint; while it would seem pretty plain talk on the part of disease if the tumor swelled when desire to urinate was felt, or if urination was followed by the tumor's disappearance, or if the patient needed to urinate before the hernia could be reduced, or if a noise could be heard in the hernia at the end of urination. Yet symptoms can speak more clearly still, as in those cases in which, in order to urinate, the patient found it necessary to elevate the scrotum and its contents, or compress it, or both elevate and compress it, as in Brodier's case, in which the hernia hung half-way down the thigh. Petit's patient needed to practise compression while in the dorsal decubitus; and Clement's, whose whole bladder was in the scrotum and would hold two quarts, had to compress while raising and rolling the tumor around. In De la Porte's case of double vesical hernia pressure on both tumors was needed; and in Ledru's case (1739), in which there were two tumors, one hypogastric, the other near the symphysis, after the former had been emptied by the catheter, compression of the latter caused fresh urination.

The two cases of Stolpert van der Weyl, in which an abscess in the groin discharged urine and calculi, are cited by Verdier as instances of vesical hernia, though the evidence seems inconclusive. But in Toscano's case such was probably the condition, as a tumor formed in the right scrotum, burst spontaneously with exit of urine and pus, and a fistula resulted through which eventually all the urine escaped. A calculus was also expelled by this route.

3. Cases in which the bladder was found in a hernia, but was recognized and not wounded.[2] In

boy, aged eighteen months, had a tumor of the right scrotum for ten months. During radical operation, urine escaped from the wound. The hernia was found to consist entirely of a very thin finger-shaped diverticulum of the bladder, firmly adherent to the cord and the inguinal canal. This was cut away, and the opening closed by suture of the muscular coats. Primary union ensued.

Foy (Lancet, 1900, i., 731) reports a case operated upon by O'Grady in 1883, that of a boy aged six years. The hernia was of one and a half years' duration, and the size of an orange. When compressed it caused urination. At the operation it was recognized as the bladder, but was deliberately opened to make sure of the relations, a catheter being passed through the urethra, bladder, and hernial opening. After suture recovery ensued.

[1] Sjovall's cases are included, though they are not tabulated, the particulars in Swedish being inaccessible.

[2] A few cases fall under two of these categories (*e.g.*, Pott's), but none are counted twice in making up the total.

[3] Cases found at autopsy: Sala, 1520, cited by Verdier. Curade, 1742, cited by Verdier. Verdier, 1769. Unnamed surgeon, cited by Verdier, 1731. Ruysch, cited by Verdier. Beaumont, 1733, cited by Verdier. Clement: "Obs. in Surg. and Pathol." Anonymous: Rust's Magazin, Bd. xxiii., p. 616. Hartmann: Graefe's and Walther's Jour., Bd. ix., p. 399. Perrin: Bull. de la Soc. forty-seven instances this was the fortunate outcome, and a consideration of these illustrates the means at our disposal for recognition of the ectopic bladder. In view of the pretty general experience of operators, its presence should be suspected when the hernial sac is of unusual thickness and weight, and especially when a large mass of fat lies to its inner side. This latter has been dignified in the literature by the term "prevesical lipoma," and this appellation may be rarely deserved. But in most instances it is merely an increase of the fat usual in this locality. Within the mass may sometimes be distinguished by a nice sense of touch the feel of two surfaces slipping on one another. Lotheissen was several times led by this sensation to suspect the abnormality, which was then confirmed by other tests. Yet we should remember Lotheissen's own observation that small cysts containing a yellow fluid may be found here.

When the displaced bladder has been encountered, it has often been mistaken for another hernial sac. This error is comprehensible, since in its false position the walls become often so thinned as to be indistinguishable from ordinary serous sacs, and so friable as to tear with slight handling. Even when the presence of the bladder has been suspected, and the protrusion examined with that possibility in mind, veteran operators have pronounced the doubtful structure a second sac, opened it intentionally or unintentionally, and found it to be the urinary bladder. If muscular fibres can be distinguished, or if a sound can be made to enter the suspected structure from within the bladder, or if its cavity can be distended coincidently with the bladder by injections, doubts will be dispelled. Yet all these tests have at times failed in the hands of able operators; and even after the bladder has been opened it has been occasionally impossible, except by outflow of urine, or by causing a sound introduced from the groin to touch another introduced *per urethram*, or by microscopic examination of the tissues, to distinguish the thinned, translucent structure from a sac formed of peritoneum. The occurrence of a second hernial sac is itself, however, so great a rarity that a safe rule would seem to be to regard as the urinary bladder any structure resembling a second hernial sac, until proved otherwise.

4. Cases in which the bladder was wounded, intentionally or unintentionally, during operations for hernia.[1] There are some ninety-three cases, including the one herein reported by myself. Wounding of the bladder has sometimes happened because its presence was unknown. The accident has then been discovered at once, or not until tenesmus, hæmaturia, and perhaps urinary fistula announced its occurrence. Sometimes the bladder has been mistaken for a second hernial sac, omentum, lipoma, or cyst, and treated accordingly. And sometimes the protruding portion of the bladder has been intentionally opened or resected.

Methods of Treatment and Mortality.—When the emergency was recognized, a variety of plans of treatment have been employed to meet it. In one of the earliest cases (Arnaud's, 1740), the wound was simply tamponed. Other operators (Aue, Schimpert, Praenischnikow, Delorme, Sebileau), fearing urinary infiltration, sewed the edges of the bladder wound to the skin, thus making a urinary fistula. If the patient recovered (Praenischnikow's died of pyæmia), this either closed spontaneously, or was closed by a secondary operation.

In eleven other instances, usually from the oft-repeated mistake of taking a bladder-diverticulum for a hernial sac, the protruding portion was ligated and cut away. In one instance (Bull's) this treatment resulted in healing without fistula, though tenesmus and hæmaturia necessitated reopening of the external wound. Four (Curtis says three) of this series of eleven cases were fatal; two after a secondary operation for removal of the ligature and suture of the bladder wound (Ostermayer, Hotchkiss). Jungengel and Michel saved their patients by doing a secondary suture. The other cases recovered with fistulæ, which eventually closed spontaneously.[1]

It is probable that many cases have been, like my own, instances of inadvertent ligature and resection of a portion of the bladder, in which, after the accident was discovered, the ligature was removed and a suturing done. But it seems to me poor practice intentionally to place a ligature of the bladder, and I cannot at all agree with Curtis' conclusion: "These results are not so bad, but that, if suture be impossible, the ligature might be considered as a means of occluding the

wound in the bladder in case of emergency; for if it can be made to hold by transfixion, its use will tide the patient over the early dangers of extravasation, provided the external wound be treated openly by packing, or at least drained by a large tube carried down to the neighborhood of the vesical wound." This practice contemplates the eventual formation of a urinary fistula, and it would seem safer and less distressing to the patient, when suture is impossible, to establish the fistula at once by tube or siphon, as in suprapubic cystotomy, rather than to place a puckering ligature, which must produce dysuria and eventual sloughing.

In the majority of cases—fifty-five out of ninety-three—the bladder wound was sutured, some surgeons placing one, some two, and some three rows of catgut or other material. This suturing failed to hold in eight cases, fistulæ resulting; all of which eventually closed spontaneously. Eleven patients died, a mortality of twenty per cent. among the fifty-five sutured cases. Two of these deaths occurred after a suprapubic opening was made to reach and close the wounded bladder; while Vincent saved a case by laparotomy and suture, in which one-third of the bladder had been cut off. The best success seems to have attended prompt suture of the bladder wound by at least two rows of catgut, the first penetrating the muscularis to the mucosa, the second infolding the edges of the wound upon themselves.

Monod and Delagénière proposed that the prolapsed portion of the bladder be frankly resected, and the resulting wound closed. Bernhard advised similarly when the bladder was thinned, and reports three cases in which this was successfully done; and Israel is reported by Zondek to have had good results from this procedure in two cases. Meienberger extirpated a ruptured bladder diverticulum, and sutured, the patient recovering; and Pilz did the same, but lost his patient from uræmia; while Garampazzi found a bladder diverticulum so adherent that he was compelled to resect and suture, success ensuing. Both Wyeth and Lanz opened doubtful protrusions merely for diagnostic purposes, and O'Grady (reported by Foy) deliberately opened and then sutured successfully a protrusion which he seems to have known to be the bladder.

These successes, while they will encourage surgeons to resect and suture diverticula with tenuous walls, which have been accidentally ruptured, or which cannot be separated from other structures, will not, however, lead them to abandon the safe rule to replace the bladder intact whenever possible.

The value of the catheter *à demeure* in these cases is problematical. Frequent emptying of the bladder by voluntary effort or catheter seems to give as good results as the retention instrument.

Drainage of the external wound is a prudent provision against leakage from the suture line in the bladder. It need, however, be no more than a small tell-tale drain. Packing of the wound, or any interference with closure of the layers advised by Bassini or Macewen, is rarely if ever needful.

Urinary fistula resulted in twenty-two of the group of ninety-three cases, in five at least of which it was intentionally established. All but two of the fistula cases resulted in recovery, the sinus closing spontaneously after a longer or shorter time; though once (Schumpert) it was necessary to close by secondary plastic operation.

Summing up results in this group of ninety-three cases in which the bladder was wounded, it may be stated that twenty-five patients died, a mortality of some twenty-six per cent. Of these twenty-five deaths, I can find but nine (Curtis found eight), about ten per cent., in which the result was fairly attributable to the accident. These were the cases of Duchaussoy, Hedrich, Jaboulay and Villard, LeConte, Guinard, Bolton, Morisani, Hartley, and Hotchkiss. The causes of death were shock, hemorrhage, urinary infiltration, sepsis. The sixteen other deaths not referable to the bladder injury were due to such causes as affect surgical results in general, and those of hernia operations in particular, viz., uræmia, peritonitis, chronic nephritis, dysentery, pulmonary congestion, etc.

Conclusions.—From this discussion and review of recorded experience in one hundred and eighty cases I conclude:

1. That the principal cause of bladder hernia is direct traction exercised through the peritoneal coat by the weight of the hernial mass, or by pull on the sac during ligation in operations for radical cure.

2. In one-sixth of the cases symptoms occur sufficient to arouse suspicion, sometimes amounting to certainty, of the existence of the abnormality.

3. In about one-fourth of the cases it may be possible during operation to recognize the bladder and avoid injuring it; and after one hernial sac has been found, any structure resembling a second should be regarded as bladder, till proved otherwise.

4. When the bladder is wounded, the best procedure is immediate suture by two layers of catgut, and closure of the hernial wound by Bassini's method; a small drain only being left leading to the bladder suture line. The bladder wall, when thinned, may be freely resected preparatory to closure.

The catheter *à demeure* is not essential to primary union of wounds thus closed.

5. Urinary fistula nearly always closes spontaneously.

6. Injuries of the bladder have been directly responsible for death in only ten per cent. of the hernia cases in which they occurred.

THE "NAUHEIM TREATMENT."

By H. NEWTON HEINEMAN, M.D.,

NEW YORK.

In 1887 I first visited Bad Nauheim and for ten successive summers spent from two to four months at that resort. The opportunity to investigate the treatment resulted in the papers read before the New York Academy of Medicine in 1890[1] and in 1896. In the winter of 1895–96, the kindness of Geheimrat Professor Dr. von Leyden, of Berlin, enabled me to make some observations upon exercise treatment, and these together with previous work at Nauheim constituted the basis of a paper read before the Verein f. Innere Medizin, of Berlin, in February, 1896.[2]

At the close of 1896 accident determined me to take up practice at Bad Nauheim. At the very outset I felt the necessity of a change in the manner of applying the treatment, which had unwittingly gone on in the old routine, and judging of the effects in not a small number of cases, it appeared to me excessive. I determined upon a course of conservatism with my own patients, which I felt should receive a fair trial, knowing that such treatment could certainly do no harm.

Four seasons, practically representing four years of personal experience, induce me again to offer the profession the results of this trial.

Historical: In the interest of historical truth I desire to do justice to a name deserving of the highest encomiums and to whose transcendent genius we owe the application of the bath treatment to cardiac dis-

[1] "Balneotherapeutics and Mechanotherapeutics of Chronic Heart Disease." MEDICAL RECORD, February 14, 1891.

[2] "Chronische Herzkrankheiten-Therapie." Verein f. innere Mediz. Deutsche mediz. Wochenschrift, 1896.

ease. In 1857 Professor Beneke, then Dr. Beneke, and instructor at the Marburg University, was called to Bad Nauheim by the authorities to practise in the summer. For several years prior he had visited Nauheim and made observations, and after eighteen months he in 1859 published the first scientific "Treatise upon the Nauheim Baths," in which he says (page 257):

"The cases of organic cardiac disease which has resulted from rheumatism or endocarditis furnish no contraindication to the use of the saline bath. Four cases above referred to of organic cardiac disease belong to this category; in none of these even a single symptom arose which could render the continuation of the bath unwise. On the contrary, I have arrived at the conclusion that the saline bath in individual cases, even if it does not produce improvement of the organic lesion, at all events can prevent its increase and relapse. I should not hesitate an instant to bathe persons who in consequence of rheumatism have become afflicted with cardiac disorder, provided that no secondary renal disease have developed, and I believe that the bath will not prove without service."

It should be borne in mind that Beneke was also a brilliant pathologist, and that the above statements would never have been made had he not found pathological evidence to support them. This gives to them a value which they have, I fear, even to-day failed to be credited with.

In 1871, August Schott, the senior brother, since deceased (1886), entered upon practice. At this time Oertel, of Munich, was writing and urging the use of various forms of exercise, when Schott adopted the resistant movements of the Ling Swedish system of exercises, and thus gave a very useful and practical form of exercises to the profession. But even here, as in so many things, "history repeats itself."

So far as the application of warmth is concerned, dry and moist warmth in the shape of baths were resorted to for cardiac disease in the sixteenth and seventeenth centuries. And at the beginning of the present century Williams and Hope both demonstrated, in the first place, that cardiac hypertrophy and other lesions could be recovered from, and that exercise kept within limits was one of the means of treatment applicable to cardiac disease. It is a matter for regret that the genius of Stokes, who recognized improvement in many of his patients with cardiac disease, who were devoted to hunting and sport, after indulgence in exercise against his own wishes, failed to do little more than simply to note the fact. Had he carried it out to its legitimate deductions, he would have formulated some mode of exercise, for the teachings of Williams and Hope, which had been lost sight of, were before him to encourage him.

General Remarks.—Mental states and suggestion in cardiac treatment: It has been remarked that in no form of illness can so much be accomplished by "suggestion" as in cardiac treatment. That mental states have a powerful influence over cardiac conditions is true, but this should not be confounded with suggestion. By suggestion we mean a state of mind disposed favorably for the good results of a certain treatment. My own experience has taught me time and again that what I must control is the avoidance of mental irritation that comes from family, financial, business, and social worries and annoyances. If I can do this, I bring to bear a very important condition for the success of cardiac treatment; and with complete freedom from mental annoyances, it then matters not whether the patient be an absolute unbeliever in the treatment applied; in short, even if the suggestion be opposed to the treatment (which is not suggestion), success generally follows. In a paper read before the Berlin Medical Society, I referred to my experience in a case which I had carefully followed. There are not a few medical men who, in speaking of Nauheim results, dismiss it with the word "suggestion." This word, which may mean so much or so little, cannot have any greater application in Nauheim treatment than it has in the entire range of medicine. We all know that the inspiration of confidence gives the patient a buoyancy that unquestionably diminishes pain and overcomes difficulties and even crises. I appeal to any member of the profession who has lain upon the sick-bed in his older years, when he had become the therapeutic cynic, whether the entrance of the colleague upon whom he relied for help did not give him a feeling of helpfulness that was appreciable. Shall we deny this to the average layman? But to accept the inference that Nauheim treatment is even largely suggestion is to be led to a conclusion without justification. The suspicion with which the profession still regards physical treatment keeps patients from Nauheim until they have tried all known medical means; a large number have tried all the forms of quackery, and a certain number come feeling that death has already claimed them, absolutely without faith and only to oblige a fond parent, wife, child, or other relative. There are a large number of children, and a not inconsiderable number of adults of wealth without occupation or care of any kind, who, with equal indifference to result except a desire to get well, try all known remedies and physicians in turn, and finally find relief only in Nauheim treatment. These latter were as much under the influence of suggestion in the treatment that failed as in that which succeeded, and as for children one could not claim suggestion here more or less than elsewhere.

In 1894 and 1895 I examined the cardiac condition of a large number of German laborers daily before and after their day's work. The German phlegmatic disposition lent itself well to the investigation, and I found that only when the mental element of hurry was added to the work could an appreciable and undoubted difference in the size[1] of the heart be recognized at night. Among those examined, I found an athletic, sober, and steady baggageman who for a fortnight failed to show any difference worth remarking in the size of the heart, between the early morn and night. One night, however, the difference had become so marked, being nearly a céntimetre, that I asked him what he had done and if his work had been unusually hard. His response was no; finally, driven by my questions, he admitted having had a wordy quarrel at the railroad station an hour previous, which was all that he had done out of the ordinary that day. It was thus proven that mental excitement had produced an amount of cardiac dilatation which his daily hard avocation had failed to produce. Dr. Livingstone, the African explorer, learned by autopsies that many of the young Africans whom he took out of their countries to use as guides, died of homesickness and had well marked cardiac dilatation. The effect of intense mental application in bringing on attacks of angina has often come under my experience.

The result of anger and various forms of mental excitement in producing cardiac dilatation or hypertrophy have been recognized not only in man but in animals as well. The late Prof. Alonzo Clark often spoke of the fact that the rooster in charge of a large number of hens frequently had cardiac hypertrophy.

It must be evident, therefore, that the patient who is being given Nauheim treatment, and who leaves the bath in the forenoon to encounter later in the day the varied forms of life's mental annoyances, can never

[1] I wish to remark here that the heart of men in active work does not maintain itself in exactly the same position from morning to night, and that some displacement is always found at night after work, and if they are well there is no difference in size worth speaking of.

hope to receive much or permanent benefit. Freedom from mental irritation, during the period of treatment and for a period after treatment, from all sources, whether from family, social, or business causes, is a *sine qua non* to its success. Exceptional results prove nothing. I do not by any means advise solitude, as is necessary at times in the Weir-Mitchell treatment, for Nauheim treatment means physical medication in which exercise of some form is an important factor.

Artificial treatment compared with treatment at Nauheim often results so decidedly to the disadvantage of the former, that the failure to obtain results in hospital or private practice is constantly brought forward to disprove the probability, yes, even the possibility of a Nauheim cure being really the result of the treatment. It cannot be expected that the former can equal the treatment at Nauheim. But any large degree of failure must even here be traced to the omission to secure the requisite mental or physical quiet for the patient at the time. Still further it is very necessary to remember that the effect of Nauheim treatment cannot always be judged immediately, unless all factors are carefully inquired into, and even then I am constantly meeting cases at Nauheim concerning whose improvement I have the gravest doubt, which doubt is at times shared by the patient; but in the majority of such cases I have been gratified to learn in the spring that one or two months after treatment, and once the patient was at home, rapid improvement of a permanent kind had set in—and to receive the news that the winter had been the best passed in years is a common intelligence, which reaches me even from the most bitter scoffers among the patients. So that, given a proper conservatism in the application of the treatment, I should hesitate in even the most doubtful cases to pronounce judgment upon the result, short of three months.

Hospital Experience.—One of the most important things to be remembered is, again, the frame of mind of the patient treated. The poor man who, lying ill in the hospital, knows his family to be starving, or who has mental suffering because of his poverty or of his family affairs, is in no condition to be helped. Let private charity step in, however, and provide for that family and smooth out his troubles, and the hospital patient will improve as surely as does his wealthier brother. Again, to expect that a diseased heart can be repaired to the extent that a hospital patient can return to work like blacksmithing or longshore work, is to expect the impossible. Here again private charity must step in to teach the laborer lighter forms of work with which to maintain himself and his family. This view is based upon my own practical experience; so that I am not surprised to read that the hospital reports as published from time to time offer little encouragement in the application of this treatment. The opportunities here for saving the labor of men who still could do some form of light work is the philanthropists' opportunity, side by side with the public sanatorium for consumptives, with fully as good if not a better prospect for success.

Private Practice. — Except as an after-treatment during the winter, after a summer passed at Bad Nauheim, the giving of treatment, say at one time of the day, while the patient attends to his business at another, will never furnish sufficient success to encourage the profession to adopt it. Even domestic relations must be inquired into, and unless there is a certainty that nothing in this direction could interfere, the patient should be sent away from home to be treated. Often even at Nauheim I have found the presence of children a serious source of irritation to the parent, so that I now insist upon their separation, and this must be considered in private practice. In private practice as in Nauheim the patient must give himself up to the treatment.

Nauheim treatment: During the past year an additional spring, No. 14, has been tapped, whose waters are nearly identical with the other two springs, Nos. 7 and 12; the temperature varying from 31° to 33° C. and over.

This has been an important addition to the existing sources for baths, and with a new bath house just building, whose level is so arranged as to secure the new spring water under its most nearly natural existing conditions, a potent increase of Nauheim's bath resources is secured.

The modes of administering the baths are still as formerly, with the exception that the new bath house when completed may furnish new grades of strength of the water.

The springs Nos. 7 and 12 are led to open and to closed reservoirs. In these they lose more or less carbonic acid and some heat, and thus from the open reservoir we draw the water weakest in carbonic acid, while from the closed reservoir the water contains considerably more carbonic acid. This constitutes an important factor in Nauheim baths—for the carbonic acid being held in three ways, by chemical union, in (as the German calls it "halb gebunden") semi-combination, and free in the water, enough remains after the free carbonic acid is lost to constitute the baths given from the reservoirs very strong thermal carbonated saline baths, technically called thermal baths.

The succeeding grades of strength of bath are furnished by using the waters of the various springs led directly underground into the tub, without intermediate exposure to the air. This is called the effervescent (sprudel) saline bath. In the latter the patient has the effect of all the carbonic acid, the free carbonic acid covering the body with carbonic-acid bubbles, which keep discharging very slowly from the surface of the body, while the body is also affected by the partly and wholly combined gas. I desire to say here that there is no danger connected with such a bath, if after the tub is filled the gas on the surface of the water is brushed aside with a towel, two or three blows answering; the subsequent accumulation of gas being insignificant. With children, however, care must be taken not to use adult tubs, else the reaccumulation may be enough to disturb them. The final grades or strength of bath are obtained by causing the waters, as in the case of the effervescent bath, to come directly from the earth to the tub without exposure, but permitting them to flow through the tub continuously during the entire time of the bath, openings for the outflow being provided in the tub at the upper level of the water. Thus, given that it takes two minutes to fill a tub, the patient who remains in the bath for ten minutes receives the stimulating effect of the carbonic acid and mineral elements contained in five effervescent baths.

This constitutes a very powerful and for some purposes over-stimulating bath.

Factors of the Bath.—The factors in applying the baths, which constitute the important elements in treatment, are:

First. The warmth and the fact that it is a natural warmth, avoiding any injurious artificial application of heat by which important elements may be dissipated.

Second. The presence of alkaline salts and of metals in large quantities; and of rarer elements whose exact value is as yet uncertain.

Third. The large quantity of carbonic acid held in an active form, and its coincident combination with the salts and other elements.

Finally. A certain quantity of electro-magnetism or magneto-electricity, which these waters have in common with certain other springs.

It is the combined presence of all these important components that constitutes the efficacy of the Nauheim waters and makes them the most potent waters in Germany. At times it is necessary at the outset to dilute the natural Nauheim waters in order to introduce the treatment without discomfort to the patient.

Temperature and duration: In this connection I must ask special attention to an error into which I had myself been led. In my papers of 1896 I recommended the use of temperatures of 33½° at the beginning and its gradual reduction upon successive days to 30°, 29°, and even 28° C. Such a course must needs bring confusion into the physiological theories that we adopt, for a bath at 28° C. is no longer a warm bath, but a decidedly cool bath, and its effect upon the skin and circulation is vastly different. For three years I have entirely abandoned any such low temperatures, and I desire to say that I begin with a temperature of from 33½° to 35° C. according to the diseased physical condition of the patient, considering likewise whether the patient be stout or lean, be younger or older, and be accustomed to cooler or warmer bathing. The temperature in subsequent baths is sometimes lowered two or three degrees, though in the majority of cases one or two degrees, in some cases less, and in a few the same temperature is maintained for the greater part of the time.

Duration of bath: Beginning with four to six minutes, I gradually increase the duration to eight, ten, or twelve minutes, increasing the time in exceptional cases to fifteen or twenty minutes. Whenever the baths are changed to the stronger form, the duration must be reduced at the outset, and the length of time finally adopted depends upon the patient's condition and his ability to bear a stronger bath, always keeping well within conservative limits. Usually it is less than the maximum duration of the weaker bath.

The weakening effects, which are sometimes noticed after a first bath of even four minutes' duration are sufficient evidence that this length of time is adequate to produce a decided effect. The proper and only guide to the proper length of bath after the first few, during which the patient becomes accustomed to them, is determined by the time when the pulse changes from a slower and fuller to a quicker or smaller one, and of course when any signs of weakness of which the patient may complain supervene. The pulse almost invariably gives the indication before the patient's sensations do.

After-treatment: The necessity for having the bath towels warm, and the taking of some liquid food soon after (even a bite during dressing may give needed support and prevent faintness), are quite important. One to one and a half hour's rest is all-important. While dozing is unobjectionable, profound sleep proves so muscle-relaxing that much of the tonic effect is thereby lost.

Length of treatment: It is difficult to decide *a priori* upon any definite number of baths as constituting a course. Ordinarily from twenty to twenty-five baths constitute a number from which a good result may be expected. Still much depends upon the age, the nature of the illness, and the strength of the patient. Then too the question of the patient's ability to return for subsequent treatment in the following year must be considered. Thus thirty and more baths may exceptionally be given. The plan preferred by me when more baths are necessary, and which is considered more conservative, is, after the course of eighteen to twenty-five baths, to order the patient to a mountain resort for one month or more of rest and change of scene and method of life; then to return for a supplementary course of several weeks' further treatment.

Another question of great importance is the frequency of the baths. The ideal mode of treatment, according to my experience, is to give a bath every alternate day; but when on account of the necessarily protracted stay the patients object, they should never receive a bath upon more than two successive days, with a rest upon the third. The combination of the two methods, of a bath first upon alternate days followed by two baths on successive days, after the second rest, in regular rotation, may also prove unobjectionable.

Physiology.—When patients with weak hearts are placed in a Nauheim bath at the usual temperature of 33½° to 35° C., they first experience a feeling of oppression over the sternum, which in exceptional cases is somewhat uncomfortable, but is never of a nature to cause the slightest concern, for it soon passes off, and becomes less in subsequent baths, disappearing entirely after a few baths. At times the oppression is more marked in the abdomen, the patient feeling either a sense of weight or of constriction about the waist. The abdominal oppression is more common in women and is often found in patients who have some intestinal or pelvic weakness. Exceptionally I have found the latter sufficiently annoying (never serious, however) to compel me to use the douche baths at first, and to fill the tub as little as possible in order to keep the weight of the superimposed column of water down to a minimum.

In most cases we find the patient's pulse getting slower and fuller in the bath and the respirations after the first few hurried respirations likewise fuller and less in number. It is not an uncommon thing for the good effects of the bath to be manifested at the end of an hour or two or later, and when a change is made from milder to stronger baths, while there are no evidences of disagreeing in the pulse at the time or shortly after, very decided effects of overtension may be noticed in the evening, seven or eight hours after such a bath. Conservatism, experience, and careful watching can alone control these conditions in a proper manner.

It is not unusual, therefore, to have a lowering of eight to twelve or even twenty beats in the bath, and later during the period of rest at home a further diminution with a corresponding increase of fulness, or, as stated, the diminution and improved fulness are recognized only after the bath during the rest or even at a later period.

When we consider that the bath promotes relaxation of the skin and dilatation of arterioles, and so relieves internal engorgement for the time being, it is not to be wondered at that in a certain number of cases in which the chest walls are so thin as to permit of unequivocal mapping out of the exact size of the heart, we find the heart occupying a lesser area in some of its dimensions, at times in all, and evidently contracted as a result of the greater ease with which it drives the blood in consequence of the internal disengorgement. Such contraction and diminution in area are not equally great every day nor steadily maintained, but are liable to ups and downs with a tendency to more or less ultimate permanent diminution. The amount of such diminution must of course depend upon the amount of dilatation to be overcome. Nor must a subsequent increase of size, when this follows, mean a loss of the improvement, for compensatory hypertrophy may in a given case be needed to supplant the dilatation and maintain the heart in a satisfactory condition.[1]

That reflex action through the nervous system plays a certain rôle in this heart change is demonstrated by the fact, well known to physiologists, that the heart can be made to vary in size in experiments upon animals. Again, in an article published by me in 1890, read before the Academy of Medicine of New York, I referred to the steadying effects which counter-irritation with

[1] Discussion before Harveian Society, London, March 19, 1896.

the galvano-cautery had when applied over the heart or liver. Heitler, of Vienna, Botkin, of Russia, and others have experimented and studied the relations of the size of the heart and other internal organs to each other; thus, that a small liver meant a small heart, and that better contractions and consequent diminution in the size of the heart denoted a smaller liver or spleen. Again the results of Roentgen pictures taken by me some three years ago, which were published by a colleague, and which, repeated by me since under circumstances of the greatest accuracy, proved the correctness of the contention that the heart could be directly improved in a comparatively short time, as evidenced by better contraction of its walls and their retraction in possible cases. Still further the recent investigations into the human cardiac reflex help to prove the possibility and thus add to the strong probability that the statements made by me that a heart may diminish its calibre under the influence of Nauheim baths are true. I desire, however, to deny most emphatically the statement that simple reflex effect upon the cardiac muscular walls constitutes the principal effect of the baths, and that to reproduce this effect by other means is to reproduce the whole effect of the Nauheim bath. As the result of the Nauheim bath we have not only the relaxation of the capillary blood-vessels of the integument,[1] but all the results, which this article will discuss, and it is this sum total of result that constitutes the entire physiological action upon which the effect is based.

Blood state: Another most important physiological change which the baths produce is the change in the quality and quantity of the blood. Winternitz and his pupils long since called attention to the effect which simple water baths had upon the circulating fluid in ordinarily depleted persons. Personal experience compels me to say that simple water baths of any duration are badly borne by patients ill with cardiac disease. Keller, of Rheinfelden, and Robin,[2] of Paris, have demonstrated that in cases of chlorosis the saline bath produces marked changes for the better in the blood state.

For the past three years I have selected two kinds of cases for such investigation, the one group in which chlorosis was the predominating factor and the cardiac and vascular weakness secondary, the other in which the cardiac degeneration was the more important, and anæmia while marked was clearly secondary.

In the cases of chlorosis the improvement in coloring matter (hæmoglobin) has varied from fifteen to thirty-five per cent., and the increase in number of the red blood globules from eight to sixteen per cent.

In the cases of predominating cardiac disorder, the hæmoglobin has increased from five to twenty-one per cent. and the average red blood globules from three to ten per cent.

I here refer to the improvement made in the course of a treatment at Nauheim lasting from five to ten or twelve weeks, the latter periods of time not representing continuous treatment, but the entire time from the beginning of a first cure through a vacation of some weeks and a second treatment of a few weeks.

This improvement in the constitution of the circulating medium and the change for the better in the pulse conditions, would of themselves explain in a satisfactory manner much of the general improvement in health which follows in nearly all cases aside from cardiac improvement, upon which the baths likewise exercise a decided influence.

Nerve Tonic.—With better blood state of course improved nerve tone must follow, and the change in the circulation in the spinal cord and body, effecting a better condition of the cord and peripheral nerves, must explain to a large extent the improvement which we so often find in spinal affections, locomotor ataxia, neurasthenia, etc. Still further the relation of the cardiac plexuses with the numerous peripheral nerves must under such conditions furnish the basis for improved reflex action upon the heart and body generally.

Electric or magnetic influence: Du Bois-Reymond, Claude Bernard, Marey, Waller, of London, v. Urbanowitch, and others have demonstrated that the cardiac systole produces as the result of the muscular contraction (oxidation of the tissue) a distinct electrical discharge capable of being measured, and varying with different conditions of the heart and the manner of measuring the discharge. This subject, which has interested me for some years, finds its greatest difficulties in the fact that the discharge cannot be measured while the patient's body is immersed in the saline bathing fluid, for the current will take the shortest and easiest route through the fluid to the other pole. By means of comparison before and after the bath, taking due precautions to get rid of the imbibed salt in the skin without adding other elements of irritation or excitement to the integument or muscles, I have found an increase of electrical discharge after the Nauheim bath. These experiments, which are of extreme difficulty, I hope to publish in detail in the course of time. The question, too, whether the increase is the result of a greater discharge or a better nerve transmission must likewise be determined. It is an important corroboration as far as it goes of the influence upon either the heart or nervous system, or both, of the Nauheim bath.

Tissue metabolism: There can be no question that the metabolic changes in the boby are affected. Thus in two-thirds of the cases the specific gravity of the urine is gradually diminished, while the quantity passed is increased. The average diminution in specific gravity is five degrees, varying from one to twelve degrees, while the largest number of changes lie between five and seven degrees. The average time required for this diminished specific gravity to reach its maximum is from fourteen days to a month; occasionally it is reached in seven to ten days. In one-third of the cases the specific gravity of the urine is raised; the average is four and one-half degrees. There appears to be no difference so far as prognosis is concerned between these cases of diminished or increased specific gravity. In a small fraction of cases there is no effect whatever upon the specific gravity, and these are usually cases in which the specific gravity is low to begin with, and in such cases I feel that the suspicion of contracted granular kidney is often justified.

The experiments made some years ago by Zuntz in his laboratory with saline baths led to a negative result, but we must recall that he took normal patients. The effect of an ordinary stimulant upon a weak or a healthy robust patient is very different, so that the above experiments require repetition under the conditions prevailing in patients to whom such treatment is administered. In cases of chlorosis, in which tissue metabolism has often been studied, the physiological conclusions agree with the good practical results obtained.

Rheumatism and gout: The important practical results obtained in cases of rheumatism and gout and their combinations, and the improved condition resulting from the baths as demonstrated in the recorded[1] experience of over fifty years' use of these baths—for formerly these two conditions were those almost exclusively treated at Bad Nauheim—speak volumes for the power of these baths to produce tissue changes resulting in improved diatheses.

[1] We must constantly bear in mind that the capillaries of the skin can harbor over two-thirds of the entire blood in the body.

[2] See article "Nauheim, etc.," by H. Newton Heineman, M.D., 1896, MEDICAL RECORD.

[1] See Bohde, Sr., on "Nauheim Baths."

Exercise Treatment.—Few cases under my care receive bath treatment alone. While the exercise treatment as limited to resistance movements has great value in many cases, I have found that a system of graded exercises furnishes the safest and best means of accomplishing the desired result. This important modification of my teachings of 1896 was forced upon me immediately after I began my own practice, by finding a small number of cases in which I could not apply even the mildest resistant movements. Accordingly I began with a "stroking massage," the effects of which I had long since learned would produce greater fulness and slowing of the pulse, in consequence of the greater ease with which the return flow of blood takes place through the venous capillaries as the result of the compression produced by the hand. The massage must be made from below upward toward the centre of the body, and from the head toward the trunk. This massage given daily, always under cover and without exposure, in the afternoon for from six to ten minutes at the outset and increased to twenty minutes, exceptionally to thirty minutes, should be followed by an hour's rest. Exceptionally we find patients complaining of cold feet after this massage. Such patients must be kept especially well covered and artificial heat applied, and if this be insufficient, then a final "tattoo" massage of the feet and limbs will restore warmth.

I find "respiratory exercises" of great importance; these the patients should be taught to do when alone. Have patients place a light cane behind their back and put both arms over the projecting ends; they should then walk with measured stride, breathing regularly and as deeply as they conveniently can at the same time. In summer or in good weather this should be done in the open air, and in winter in the house in a well-ventilated room.

Resistance Exercises.—These follow after a week or fortnight of massage and respiratory exercises. The old rules as formerly given are:

First: To make all movements and resistance steadily and without jerk.

Second: Not to repeat the same movement in succession.

Third: To vary the nature of the movement as much as possible.

Fourth: To stop when hurried respiration or quickened pulse indicate fatigue.

To these rules I wish to add the following:

First: Resistance movements do harm if the patient has not been taught to breathe regularly at the same time, and to avoid holding the breath. Holding the breath during the movement produces dilatation of the heart, especially when the cardiac muscle is already impaired.

Second: In heavily built and stout persons certain movements may produce intermittent heart action. In women they are often those of opening the extended arms, sometimes the leg movements, and in both sexes often the trunk movements, particularly of the left side. These must then be omitted. Sometimes the patients can undertake even these exercises later, having gained muscular strength and adroitness, and particularly because they have learned the task of coincident, regular respiration.

Third: Never seek to produce immediate results; a forcible resistance which fills the pulse is apt to be followed by a harmful relaxation. Begin with moderate resistance and do not permit the patient to dictate the amount. After months of treatment, when the muscles have acquired tone, decided resistance may be resorted to, provided it is comfortable to the patient.

Fourth: Use no movement that carries the hands above the level of the shoulders, and particularly not above the head. This fact rests upon well-established physiological data proving that, when the hands are raised, arterial tension[1] is increased and the action of the heart weakened and made slower. This is caused by the force of gravity acting with increased vigor against the heart.

Combined exercises: Not infrequently I find that eight to ten minutes of stroking massage, given after twelve to fifteen minutes of resistance exercises, has a most quieting and soothing yet stimulating effect upon the patient. The succession and combination of massage, respiratory exercises, and resistance exercises, the length of time which each form is to receive, must be decided by taking into consideration all the elements of the case, and our personal experience. While mere caprice should never influence a physician in his decision, decided aversion or extreme discomfort must be considered in recommending massage or exercises, and the time of administering them. I have met with patients with unbearable aversion to massage and some with inability to exercise properly. One rule should never be violated, and that is, never to give exercises in the same forenoon with a bath; as well give two doses of a medicine (ordered thrice daily) to save the time and trouble of taking the second dose.

Hill and stair climbing: In cases in which we are dealing with fatty heart, I find that after the patient has been under treatment for a course of five or six weeks and then returns after some weeks' rest for a second brief treatment, this form of exercise can be introduced after a week's use of the general exercises; provided, of course, the patient is, generally speaking, suffering from no untoward symptoms. One can commence with a short walk of one hundred, one hundred and fifty, to two hundred and fifty feet up a moderate incline, stopping every thirty, forty, or fifty feet for rest and to take a few full respirations. It is important that the patient breathe quietly and regularly during this entire exercise. If the patient cannot do this, the exercise will do harm. It is evident, therefore, that such exercise can be used only with the supervision of the doctor or a reliable assistant, who must determine by the pulse and his own observation of the respirations the ability of the patient to do more or less. Here again the rule of not increasing the amount of exercise from day to day too rapidly is most important. Time to accomplish safe results is of the first importance. An ultimate walk of five hundred to one thousand feet is ample for all purposes, the nature of the incline being varied when the patient gains sufficient strength.

Stair climbing is a very useful mode of exercising. The patient is taught to mount at first two, three, or four steps, resting with both feet on the step long enough to take a few good breaths, before mounting the next. This can readily be substituted for outdoor exercise in bad weather.

General rules: I repeat as of sovereign importance that in all forms of exercise regular respiration is absolutely essential, and an important essential is to resist the patient's ambitious desires and one's own inclination to press forward and so go too quickly, and to attempt too many forms of exercise. It is never safe to give too much exercise upon any one day, and this is particularly to be avoided upon the day of the bath.

Here as in the bath treatment we seek for the cumulative effect of the completed treatment or of sufficiently long periods thereof. We gauge excess daily or from minute to minute, we measure success by intervals of days or weeks or ultimate result.

Physiology of exercise: All forms of respiratory exercise improve the cardiac action by better aeration of the blood, by the stimulating effect which the improved blood has upon the cardiac nerves and the heart

[1] See Marey, "Circulation," p. 341, sec. 221.

muscle, while the substance of the muscle is better nourished and thus stimulated to better contraction; also through the momentous influence of improved aspiration by which the venous return is facilitated; and finally, by all the good economic or metabolic results that flow from improved respiration.

The stroking massage, as has been already indicated, helps the venous return by directly promoting the return flow through the superficial veins compressed, and I have repeatedly demonstrated in my clinics in former years that with ten minutes of such massage a quickened pulse in a case of cardiac disease can be reduced in frequence and improved in volume. Resistance movements, by contracting the muscles, drive the venous blood on, cause a greater afflux to the part, and promote deeper and better respiration.

The direct influence of these factors is sufficient to enable the heart to act more forcibly, yet more quietly, to contract down, and to tend to overcome cardiac dilatation. The vasomotor nervous system, which controls the relation of every part of the body and the general and local blood supply, under the influence of reflex action is also stimulated to a more healthful action through the reflexes which the exercise arouses.

Artificial Treatment.—The value of artificial treatment for those to whom Nauheim treatment is inaccessible, if administered with the surroundings and under the conditions stated by me as necessary, cannot be denied. The value of alleviating half of the suffering for those to whom this or nothing is the ultimatum, requires no discussion. Without desiring to prolong this paper, I must again refer to the adoption of some form of apparatus by which the carbonic acid is so mixed with the artificial salt solution as to resemble, to some extent at least, the intimate natural admixture at Nauheim. The carbonic-acid gas is thus made active, instead of simply being allowed to pass over the body as it does in the ordinary chemical effervescence, and, what is more important still, it is only by such means, by which the exact amount of carbonic acid present can be determined, that accurate and exact knowledge of this subject can be secured. The older chemical methods of preparing artificial baths have been given in previous papers. Germany, Austria, and France, in all of which countries special forms of apparatus exist for making artificial baths, make use of very elaborate systems to produce this result. The apparatus of the Nauheim Artificial Apparatus Company of New York, which is in use there and which is employed on the Continent in a few establishments, is worthy of reference. Its ready portability and convenience, and the fact that it can hold sufficient gas and salt for three baths of a one to one and one half per cent. carbonic-acid gas and a two to three per cent. saline strength, recommend it strongly.

Dietary Rules.—From the very outset of my own practice in 1896–97 in Bad Nauheim I found that the vague and uncertain directions as given by me in my article of 1896 before the Verein f. Innere Medizin, and before the New York Academy of Medicine, required serious amendment. More is required than simply to see that the patient takes only food that agrees with him, generally speaking.

Recognizing as I had previously in general practice that many of the acute symptoms of a patient, whether burdened with cardiac or any other disorder, depended upon improper diet, imperfect digestion, and their consequences, I had when commencing practice in Nauheim but to recall my own previous experience[1] to be forcibly reminded that exact directions were necessary in these cases. Particularly in those ill with cardiac disease, it is malassimilation which has ultimately produced the diathesis which gives rise to the vascular degeneration, as well as to the train of acute symptoms against which only a strict régime maintained over a long period can avail.

Drinks: Alcohol is the worst enemy with which we have to contend, and in all persons under sixty years of age (with few exceptions) should be excluded. In older persons who have been accustomed to wine or stimulant all their lifetime, a tablespoonful of whiskey diluted at the noon (?) and evening meal may be indulged in. Time and again I have seen attacks of angina grow markedly less when alcohol was rigidly abstained from.

Coffee is likewise contraindicated, particularly if some alcohol be allowed. Occasionally when tea disagrees and cocoa is unpalatable, a little coffee in considerable milk in the morning is not objected to. Milk is above all the beverage; weak tea once a day may be recommended, and cocoa if not too richly prepared.

In arteriosclerosis the diet should be largely milk, not less than two to three litres daily. Starchy food should be avoided and bread in even very small quantity; the soda biscuit is preferable. Eggs when well borne and cream cheese (pot cheese as it is called in America) may be indulged in. Somatose prepared from milk (not from meat) and some of the similar preparations can be made use of to add readily digested food to the dietary list.

In cases requiring a less rigid diet white meats and green vegetables and the easily digested white fish (with scales) may be resorted to under the doctor's directions. In cases of fatty people with fatty heart, starchy and fatty food must be avoided; lean meats and fish, green vegetables, tomatoes, salads without oil or vinegar dressing may be used. In all cases water and soup in large quantities should be interdicted at meals for persons with fatty heart, provided they are also allowed solid food in any quantity. Between meals liquids may be freely indulged in.

In regulating an anti-fat diet, it is still a matter requiring proof that a severe diminution of adipose tissue can be accomplished without serious loss of albuminoids of the body, and though Dapper[1] remarked that *a priori* we cannot count upon such a favorable result (*i.e.*, loss of adipose without albuminoid loss) with any degree of certainty, still Zuntz's important injunction made years ago when discussing the subject of "Dietetics in Heart Disorder" is still imperative today: "In heart disorders in which paralysis of the overworked heart muscle must always be feared, besides the proteid food essential for keeping up the heart well we must see that moderate quantities of carbohydrates are constantly in the body." My own labors in the field of tissue metabolism which have been carried on for over five years firmly support his view.

It is impossible to give rules to fit each individual case. In like manner it should be remembered that just as cases of arteriosclerosis and those of fatty heart differ in the greatest possible variety, the relation of habits of life, age of patient, and constitution to the different degrees of degeneration call for so many varieties (medically considered) of patients, that all the surroundings should be taken into consideration before deciding upon a rigorous application of any form of diet. Excessive and ill applied severity may weaken and undermine the patient's physique and permit the disease to grow worse instead of better. It is also proper here again to inveigh against the constant self-experimentation in obesity cures, which so often leads to the most serious results.

Prognosis.—While it happens in about one-fourth of the cases that immediate improvement in some direction follows even after the first baths, and more often as the course of treatment advances, in fully one-half

[1] "Treatment of Chronic Cardiac Disease." MED. RECORD, 1896.

[1] Zeitschr. f. klin. Med., Bd. xxiii., Hft. 1 and 2.

of the cases improvement can be determined only by the physician's examination. The condition of the heart, of the kidneys, the relief from internal congestions, the improved condition of the blood, and better qualities of the pulse furnish data by which the gain is to be measured.

That a change in surroundings, in diet, and the more rigorous diet and even the moderate self-abnegation which devotion to the treatment calls for, should at times cause the patient to think that he feels less strong is not to be wondered at. But ten days' or a fortnight's rest in some cheerful mountain resort after the treatment soon dispose of this sense of diminished vigor. I desire here, however, to inveigh against that weakness produced by over-treatment, whether prolonged or of the too severe kind; such weakness, if the patient is strong enough, may be recovered from, but should any accident or complication supervene serious results may and do follow.

When proper conservatism is resorted to, improvement follows rapidly, and it is rare that nearly all (over ninety per cent.) of the patients do not find some improvement in the course of the winter succeeding their treatment, and in most cases improvement of a decided kind. Experience has found this observation to be so constantly correct that with a just measure of the treatment one can almost predict in a given case the amount of improvement likely to follow. It is certainly interesting to note such results as are given in a letter from a patient who had suffered from extensive myocarditis, and who for several years was practically bedridden and under the care of distinguished physicians, so that we can admit that no recognized plan of treatment had been omitted. He writes five months after the treatment at Nauheim: "I am stronger and better in many ways than I have been for ten years."

To speak of the improvement in detail:

Blood state: Hæmoglobin is increased and with it more fully developed red blood cells appear.

Heart: That portion of the heart which has yielded to dilatation is likely first to receive the impulse to recontraction and to hypertrophy of its tissues; thus we have improved contraction of the weakened portions of the heart and finally a certain diminution in size in some cases, provided compensatory hypertrophy does not finally replace the previous area occupied by the dilated heart muscle. Thus while the tendency is to general diminution, inasmuch as better contraction implies this, yet this does not go on in any steady manner, diminutions and relaxations or enlargements succeeding each other, the dilatations or relaxations becoming less; and ultimately the final result as to the heart's size is determined, as already said, by the amount of hypertrophy induced and made necessary to effect permanent improvement. Beneke had opportunities of making autopsies in cases in which endocarditis had been recognized and had been known to follow previous rheumatic infection. In accepting his dictum, therefore, that endocarditis is improved by the Nauheim baths, we are following in safe footsteps. The effect of treatment was also evidenced to me in an autopsy upon a case in which pericarditis had been recognized a year before the patient came under my observation. The usual retraction of the chest wall, which was distinct when the patient was first seen, disappeared after a time, and at the autopsy made some months after treatment the pericardium could be peeled off almost as easily as if the lesion was of recent date, while about the lower half of the left ventricular surface, where the pericardium was non-adherent, evidences of old pericarditis could be recognized. It is a record of fact whose value must be determined by additional observations, whether the diminished firmness of the adhesions were actual results of treatment or simply accidents.

Internal viscera: They are relieved of their congestion and are thus found smaller. In fact, in making my examination of a heart at the outset, the condition of the viscera, particularly the liver and spleen and kidneys, give me a better indication of the heart force than the direct examination of the heart, and this holds true constantly, provided disease of the liver can be excluded. In this connection the frequent examination of the urine must not be overlooked, for the strength of my bath and the continuation of the treatment are often determined and measured by the condition of the kidneys. While a few casts or a little albumin of a secondary character do not contraindicate treatment, yet increasing albuminuria is always a warning sign for prudence, if not discontinuance of treatment.

In the present still disputed condition of the theories concerning the rheumatic and gouty diatheses, even metabolic experiments would leave us in the dark to a certain extent as to the exact explanation for the improvement, but that rheumatism and gout are ameliorated and disappear under this treatment is a matter that has long since been practically proven. The absorptive power of these baths, or the effect they have in causing disappearance of inflammatory exudate in the body, whether in the thorax or abdominal or pelvic cavity, is a matter of very old and long-standing observation, so that years ago pelvic disorders were among those most commonly treated.

Any number of articles have been written upon the subject of Nauheim, many of them I regret to say based upon insufficient data, and I take pleasure in quoting from one whose author, Prof. George L. Peabody, after a careful investigation at Nauheim referred to the prognosis in the following words:[1]

"I am convinced that its power in heart cases justifies us in giving it very serious consideration. It is certainly a great deal to be able to relieve distressing and even dangerous symptoms, and to enable people to work who have been led to believe that their days of usefulness were over, as it is also to enable those who are working with undue fatigue and weariness to accomplish their daily tasks with less effort or even with pleasure."

Indications for Treatment.—Rheumatism and gout.

Inflammatory exudates; whether pleuritic, abdominal, or pelvic.

Nervous disorders; functional and incipient organic spinal disorders, spinal congestions, neurasthenia, locomotor ataxia in its early stages. Chorea. Sciatica and certain forms of neuritis.

Circulatory disorders; the conditions produced by chlorosis, hæmophilia, and Barlow's disease. Arteriosclerosis not in its final stages, and aneurism only in its incipiency. Varicose condition of veins. All vasomotor disturbances.

Cardiac disorders; myocarditis and fatty heart. All forms of loss of compensation, whether dependent upon muscular changes or valvular disease. Angina pectoris. All forms of functional cardiac disorder.

Contraindications.—Chronic Bright's disease. Aneurism in any advanced form. In serious cases of advanced arteriosclerosis the utmost conservatism and personal watchfulness can alone exceptionally justify treatment, which at times yields surprisingly gratifying results.

Conclusions.—No form of treatment in the range of medicine, which is applied to chronic disease and often apparently hopeless cases for whom distinguished skill and money has done everything available, can show a larger number of improved patients whose energy has been restored in various degree and whose lives have been prolonged for indefinite periods of years.

[1] "Five Weeks' Experience at Bad Nauheim." MED. RECORD, November 19, 1898.

Failure, or rather failure to achieve the desired improvement, sometimes results from the patient's indifference or inability or badly advised course in not

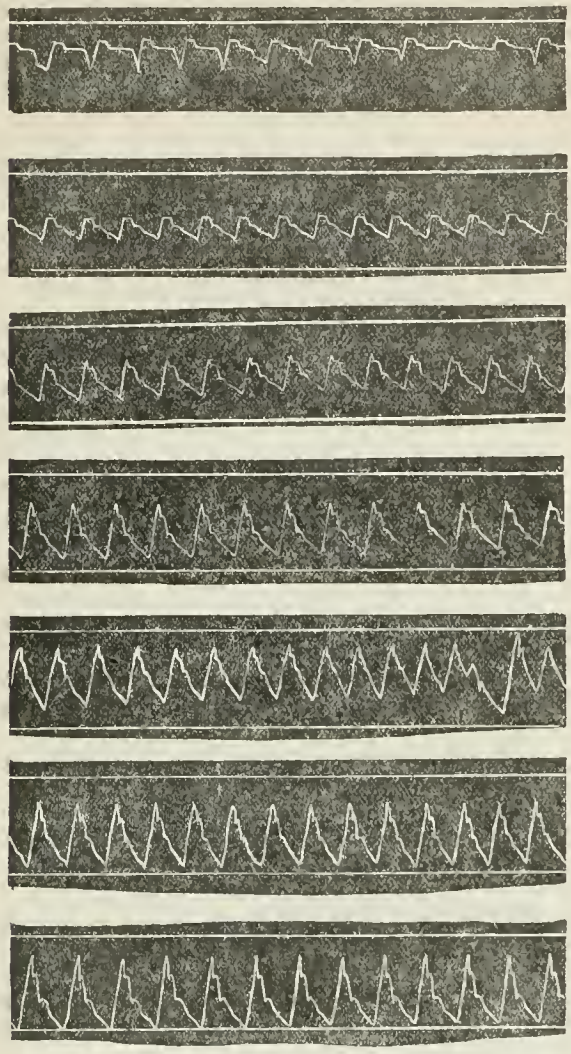

Chart 1.

repeating the treatment during the succeeding year. Here again I wish to warn against the natural inclination of too rapidly increasing the strength of the treatment in some such cases, even upon subsequent visits or courses of treatment. The same conservatism applied a second time may be equally necessary in serious conditions. And even in those in which increasing vigor of treatment may be resorted to, the increasing severity must be determined by experience and a careful weighing in the given case of the probable after-effect as well as the immediate result. In selecting the character of the bath and its temperature we should keep clearly in mind that cool baths produce different physiological effects from warm baths. Experience alone can determine whether in a given case further improvement is best secured by a continuance of the same warm bath, or whether the simple general tonic effect of a cooler bath would add to the result. But the distinction between such kinds of treatment should always be kept clearly in mind, if increasing experience is ever to lead to definite scientific conclusions and accurately measured treatment.

In weighing the value of all the various systems of treatment that are now misleading the public and the profession, it is important to remember that the production of a cardiac contraction, or of a single similar phenomenon, by this or that means, and the founding of a system of treatment upon it, is certain to bring physical therapeutics into discredit.

Step by step the effects of simple water baths and medicated baths of all sorts have been tested, and the most careless perusal of foreign literature will furnish no end of information about the effect of every kind of medication; little by little massage and resistance movements have been studied and their separate value has been noted; with the utmost painstaking the Nauheim system has been formulated and has fought its way, and to-day we know that it is by many different avenues that Nauheim treatment produces its effects. None the less, with a sublime disregard of all that has been proven and done, systems based upon a single phenomenon present themselves for adoption. The failure to give the matter the attention it deserves by proper instruction in our colleges must be responsible for such ill-formed ideas. Few of the colleges in my country have imitated the recent steps of European universities, in which in the future "physical therapy" is to be a separate study. It is thus only that the chaff can be separated from the wheat, and the valuable in physical therapeutics be preserved to the American profession.

Addendum: A few cases will serve to illustrate remarkable results in cases in which all other treatment had proven unavailing.

X——, aged sixty-two years, clergyman, widower, came to Nauheim May, 1898. He was of gouty ancestry, moderate in the use of alcohol and tobacco, had no gout or rheumatism, but had passed through the diseases of infancy. He was never robust, but always active; had dyspnœa in youth in climbing hills. He was subject to gastric and hepatic attacks since youth. Three years ago he had influenza, followed by aggravation of his old-time dyspnœa and cardiac palpitation so as to prevent moderate stair climbing. He went south and improved, but in a year's time matters grew worse so that the dyspnœa was constant upon the slightest exertion. He had attacks of angina, associated with severe abdominal pressure and a sense of cardiac expansion and of hot water flowing into the heart, and he was often unable to walk. Gastric and liver troubles were aggravated of late. He often is threatened with syncope, which he has had periodically for years. Now he is anæmic, pale, and jaundiced; has a coated tongue and sluggish bowels; complains of dyspnœa, palpitation, and cardiac sensations as above; is liable to syncope, flatu-

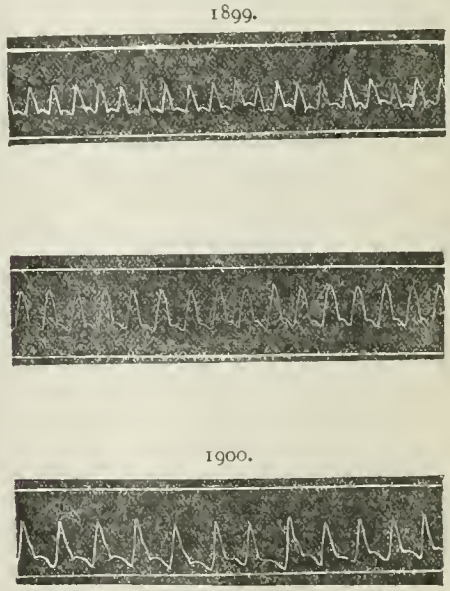

Chart 2.

lency, and gastric overdistention. Examination reveals advanced general arteriosclerosis. The heart is en-

larged, irregular in rhythm, and intermittent. The heart sounds are muffled, almost inaudible; dilatation is marked, particularly on the right side; there are moderate old hypertrophy and loss of compensation. Beats, standing, 134; lying down, 116. He has considerable emphysema and an old bronchitis. Urine, 1,330 c.c.; specific gravity, 1,022; contains a mere trace of albumin and biliary coloring matter, otherwise negative. Diagnosis, arteriosclerosis, myocarditis. The diagnosis was confirmed by that of Balfour and Finlayson, of Glasgow, who in October, 1897, recognized a weak, degenerated, and dilated heart. Within forty-eight hours after the first bath was given, the pulse had gone to the opposite extreme of 48 to 60, according to the position of lying or standing, though the slightest exertion would send it above 100.

A few days later the patient again had repeated threatenings of his old syncope. Later the pulse, which at first could not be counted on account of the reduplication and irregular rhythm and intermittency and rapidity, remained with few exceptions during the day sufficiently slow and sufficiently regular to be accurately appreciated, and it now became alternately bigeminous and trigeminous in successive beats, with a tendency to equalization of strength of beat.

The improvement is recognized in the series of sphygmographic tracings in Chart 1, taken before, during, and at the close of treatment at the end of six weeks. Before leaving Nauheim the patient was warned to forego preaching and parish work and to spend the winter in the South. He persisted, however, in facing the rigors of the Scotch winter, with a break of a few weeks, and continued his work.

He returned to Nauheim in 1899 and was again improved (see the first pulse trace in Chart 2), and again in the summer of 1900 with a further gain as shown in the lower trace. He had kept up his winter work fairly well; against my advice, however.

Latterly, January, 1901, the patient reports himself well, having gone through a serious carriage accident in which he broke an arm and had some severe sprains, yet without visible effect upon his heart as reported by his doctor.

Balfour and Finlayson considered the case one of grave import and with but little chance in 1897.

Of a case of mitral stenosis in a woman (July, 1899), who had suffered since youth and who latterly had complained of the usual præcordial pains, dyspnœa, hæmoptysis, and in whom drugs failed to give relief, her doctor, writing some time after her return, said:

"1. There is improvement in the general appearance and nutrition. 2. Ability to perform muscular exercise has returned and increased. 3. The physical signs are improved: (*a*) the tone of the ventricular wall, as evinced by the condition of the apex beat, is good. (*b*) The presystolic murmur is better heard, owing to better muscular power of the heart. (*c*) the cardiac action is regular. This improvement has been maintained to date."

A third case of myocarditis with aortic dilatation and arteriosclerosis with severe angina occurred in a man fifty-six years old, American. His father and brothers died of apoplexy and cardiac troubles. The patient has had gout, has been an excessive smoker for many years, and overindulged in athletics. He had had no influenza. For years he had a distinct sensation of restraint and oppression over the chest. Six years ago he was suddenly seized with angina, with intense dyspnœa, sternal oppression, and later pains radiating into the left hand and arm. Gradually he suffered from more or less constant præcordial pain, which became of the above acute character after dinner and upon walking against the wind. He never suffered from indigestion. He had præcordial pain radiating into the arm when taking a morning douche. He can ride a bicycle without discomfort, but pain returns on walking. Of late the discomfort has gone to the point of despair, the patient feeling that unless he could secure relief his life's work was ended. Under the care of a sagacious and interested practitioner all remedies were tried without avail, and as a last resort he was sent to Nauheim. He had not smoked for six years, since the above attacks began. Upon arrival at Nauheim examination reveals advanced arteriosclerosis. The heart sounds are feeble; first sound long and dull, second sound accentuated. The heart is enlarged; the pulse small, irregular. At times a systolic murmur is heard. During the following winter the patient steadily improved, and returned in the summer of 1899, but not in 1900. Since his first treatment in 1898 he has had practically no medicinal treatment, and his symptoms have subsided so that he is to-day in better health than he has been in years. In a fourth case of myocarditis and arteriosclerosis, the patient, nearly sixty years of age, was bedridden in consequence of his inability to make even the slightest exertion without danger of acute cardiac dilatation. After six weeks of treatment (1900) the patient, after an interval of three weeks, returned for a second three weeks' treatment. The accompanying pulse trace (chart 3) shows the cardiac

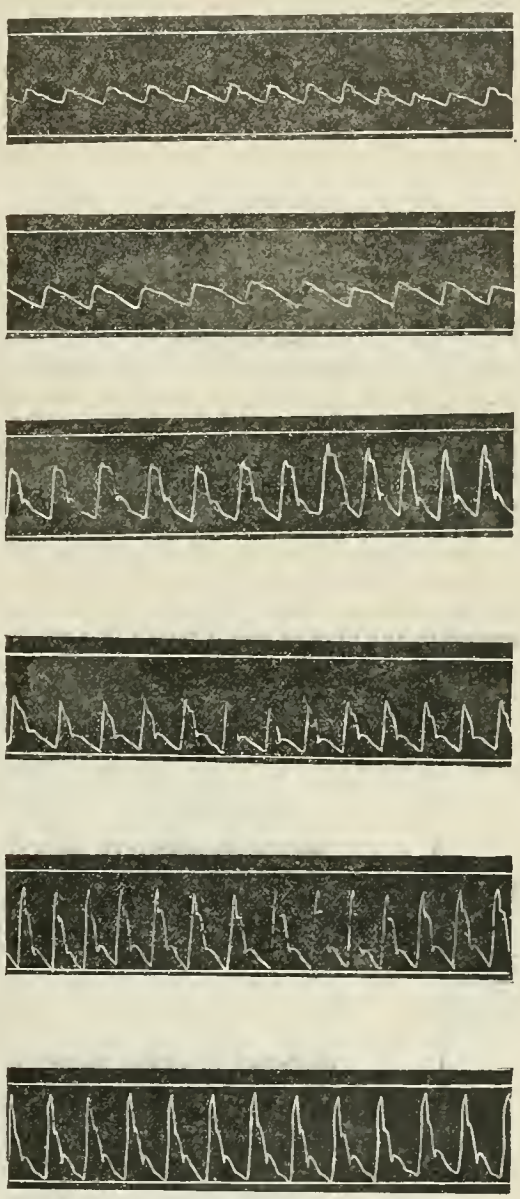

Chart 3.

improvement. The first three represent the first treatment, the fourth the beginning, and the last the close of the second treatment. At times during both the first and second treatments slight overexertion in walking caused heart failure sufficient to give rise to moderate pulmonary œdema, which was not always appreciable to the patient, but sufficiently threatening to induce me to order him to bed for some time. Within two months of the patient's treatment, he was able to take long walks without fatigue or injury, and in January, 1901, he expressed himself as better than he had been in ten years, he meanwhile having taken up his normal daily life. In this case likewise nothing that medical science could do had been omitted by his distinguished advisers.

Bad Nauheim, 1901.

ON NEPHRORRHAPHY WITH FLAP FIXATION.

By ARNOLD STURMDORF, M.D.,
NEW YORK.

The merit of any operative procedure for the cure of wandering kidney can be decided only by the permanence of the anchorage secured. That such permanence of result is frequently established, in a certain proportion of cases, by some of the modern methods of kidney fixation is fully recognized.

Statistical data on this point being unavailable, a casual inquiry among those experienced in this class of cases, as to the ultimate condition of such patients as have undergone nephrorrhaphy, elicits the fact that the choice of a technique affording the greatest promise of permanent cure is still a point for controversy. Consequently any plan or modification that guarantees

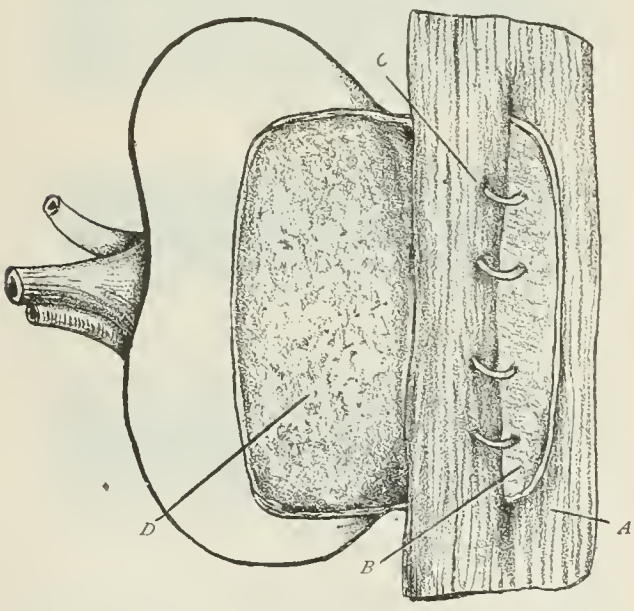

Fig. 1.

an additional element of security against ultimate recurrence of the dislocation should receive due consideration.

In the Medical Record of February 23, 1901, we find an article by Dr. Robert T. Morris, entitled, "A Method of Fixation for Loose Kidney"; the essential features of which are embodied in the following quotation:

"About two years ago, in reading over some foreign journals at the academy library, I found mention of a method for fastening a loose kidney by turning up a flap of the fibrous capsule and drawing it through a slit in the psoas muscle. I made a note of the method at the time without keeping the name of the author in mind, and since that time have been unable to find it. I have received letters from several physicians asking about my operation, as this is the one I have performed in all my cases for the last two years, but I wish to state that I have no claim upon the operation, except that it was adopted as one that seemed rational, and that up to the present time it seems to me to be the most desirable one.

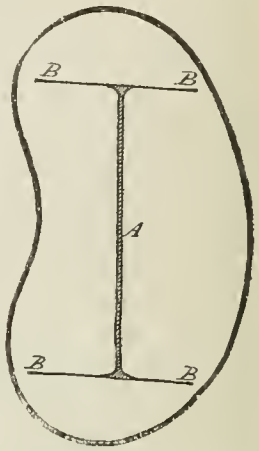

Fig. 2.—Lines of Incision in Capsula Propria. *A*, Longitudinal incision; *B*, lateral incisions.

"In this operation a flap of capsule including the larger part of the mesial surface of the kidney is incised with a scalpel, and the flap of capsule then stripped up from the parenchyma but remaining attached at the convex border of the kidney. The flap of capsule is drawn through a slit in the psoas muscle or in the quadratus muscle, indifferently as one chooses, and is there sutured in place. This brings bare parenchyma also in contact with the psoas or quadratus fascia, where it forms a firm connective-tissue attachment. The operation certainly avoids the necessity for passing sutures through the parenchyma of the kidney, and I have had no reports of recurrence of loose kidney up to the present time. It is not possible to keep track of all of one's cases, and in writing to forty or fifty patients for post-operative reports, several letters are required on an average for each patient, so that it gets to be quite a serious matter; but all patients or their physicians have been asked at the time of the operation to report any recurrence."

The operations in vogue for the cure of nephroptosis aim by various methods to secure firm broad cicatricial union between the denuded surface of the kidney and the contiguous abdominal parietes. The operation described by Dr. Morris differs from those usually employed in the following features:

First, in the utilization of a flap of capsule, in addition to the production of adventitious tissue for the purpose of securing a permanent mooring of the kidney.

Secondly, in the omission of the usual transparenchymatous sutures.

It will readily appear that the capsule flap, as a means of permanent suspension, aided by cicatricial adhesions, offers decided advantages over methods depending upon cicatricial adhesions unaided; but Dr. Morris' communication does not make it apparent that this advantage is attained to the fullest extent.

Dr. Morris' diagram here reproduced shows a single flap of fibrous capsule, *B*, separated from an area of kidney tissue which represents nearly two-thirds of the surface of that organ. Such a flap for formation is hazardous, and its employment risks defeat of the purpose in view. For, in the first place, owing to its great width, the free margin of such a flap is carried so far from its blood supply as to endanger its vitality and favor its ultimate disintegration. In the second place, the base of the flap remaining adherent to the convex border of the kidney forms a hinge joint, which will naturally favor a swinging of the inner border of that organ in the direction of least resistance; namely, forward and outward.

This forward and outward rotation must necessarily result in a separation of the very surfaces which it is

intended should be maintained in close apposition for the purpose of securing ultimate fibrous union.

It would seem that this last-mentioned disadvantage of such a flap formation could be obviated by the introduction of transparenchymatous sutures; yet it is distinctly stated by Dr. Morris that "the operation certainly avoids the necessity for passing sutures through the parenchyma of the kidney."

That such sutures properly introduced are harmless has been abundantly proven. Tuffier (quoted by Edebohls) has demonstrated "that destroyed or ablated kidney tissue is readily and speedily replaced under ordinary circumstances by a liberal regeneration of new kidney structure." Furthermore, the favorable results obtained by such parenchymatous retention sutures have been emphasized by Edebohls in a very elaborate essay on "Movable Kidney" (*American Journal of the Medical Sciences*, March and April, 1893; also *American Journal of Obstetrics*, February, 1895).

Deliberating upon the additional security against relapse which a well-devised flap operation would assure, I devised a plan of procedure, and employed it shortly after, as follows:

Patient S. K——, age nineteen years, servant, unmarried; has complete nephroptosis producing marked symptoms, and also chronic appendicitis. (The removal of the appendix by the usual interval method, which was carried out at the same time, will not be described.)

Operation, April 23, 1901, Drs. M. S. Kakels and H. S. Stark assisting. The patient was placed in the Sims position with cushions so arranged as to cause a marked upward arching of the right renal region.

An incision was made obliquely downward and somewhat outward, extending from the lower border of the last rib at a point corresponding to the edge of the erector spinæ group to the iliac crest and through to the perirenal fat.

Strong lateral traction of the wound was made so as to expose as much of the perirenal fat as possible, which was separated bluntly from its surroundings.

Incision of the fat capsule was made along the whole length of the kidney, the edges of the incised fat capsule being drawn out of the wound as far as possible, and this redundant fat being ablated on both sides flush with the bottom of the wound.

The ablation of this fat tissue is absolutely essential to secure proper coaptation between the exposed kidney surface and the contiguous parts.

To this point it will be observed the method followed that described by Dr. Edebohls in the publication mentioned above.

The formation of the flaps was now undertaken in the following manner. The kidney was pushed as near to the surface as possible, and steadied there by pressure exerted through the abdominal wall by the hand of an assistant. The capsula propria was incised longitudinally, exactly in the median line to within about three-fourths of an inch from either pole. A pair of closed curved, blunt-pointed scissors was introduced beneath this capsular incision, and the capsule was carefully separated from the kidney substance for an area corresponding to the longitudinal capsular incision in length and to the lateral borders of the kidney in width. The free capsule was now raised by mouse-tooth forceps; two flaps were formed with blunt-pointed scissors by slitting the capsule laterally at each end of the longitudinal incision, as shown in the diagram.

The flaps were secured in the grasp of T-shaped forceps, while two silkworm retention sutures, equidistant from each other and from either pole of the kidney, were passed through skin, superficial fat, the tendons of the abdominal muscles, the cut and trimmed edges of the perirenal fatty capsule, the fibrous capsular flaps, and the parenchyma of the kidney, at a depth of about three-fourths of an inch from its surface, and left untied for the time being.

The object of these sutures was not only to aid in relieving tension but to obliterate any possible hollow spaces, thus obviating the necessity for drainage, and at the same time securing firm coaptation of broader surfaces for subsequent cicatricial union.

Longitudinal slits, corresponding in location and length to the position and width of the fibrous capsular flaps, were next made through the adjacent muscular tissue, and the flaps drawn through these slits were secured in place by a running suture of fine chromicized catgut.

Three interrupted sutures of No. 3 chromicized gut were next passed so as to embrace muscle and kidney substance at a level with and equidistant from the above-mentioned silkworm sutures, and tied.

The final suture included skin, superficial fat, and fascia, after which the silkworm sutures, originally left hanging loose, were drawn taut by means of shot and plate. Primary union occurred, the removal of the silkworm sutures being effected on the eighth day.

It would seem unnecessary to state that it is not the case but the method employed which is here submitted. From all theoretical considerations based upon a study of the results of the most approved methods of nephrorrhaphy, the operation depicted above should secure results the permanence of which is guaranteed in proportion to the integrity of the capsular flap; for by this method we obtain not only all of the advantages of cicatrical adhesion, but, in addition, the effectual retention secured by what might be termed an artificial suspensory ligament.

106 East Sixty-second Street.

Two Cases of Acetanilid Poisoning in Children from Absorption from External Wounds.—Jacob L. Manasses reports two cases in which the use of acetanilid as a dusting-powder on wounds caused poisoning which was manifested by cyanosis, subnormal temperature, feeble and shallow respirations, dilated pupils, weak, rapid heart, cold extremities, and cold perspiration, with marked prostration. Treatment in the first case consisted of hot baths every four hours, followed by hot applications to the extremities, with the internal administration of whiskey in ℥ v. doses every hour. The patient was an infant of six weeks, and recovered in three days. In the second case, which was less severe, acetanilid was continued, as an artificial scab had formed, and the depressing effects were counteracted by strych. sulph. gr. $\frac{1}{5}$; spiritus ammon. aromat., spts. vini gallici, āā ʒ ii.; elix. aromat. q.s. ad ʒ iii. One teaspoonful every hour. The child, a boy of two and a half years, recovered in two days.—*International Medical Magazine.*

Puerperal Influenza and its Differential Diagnosis.—M. Stolz bases the following conclusions on forty cases of epidemic influenza complicating childbed, observed during the spring months of this year. The course run by the disease is usually mild, a circumstance perhaps depending on the fact that the patients are in the reproductive age and therefore have good powers of resistance. The influenza usually appears on the third or fourth day after the supposed exposure to infection, though sometimes not until as late as the ninth day. Three general types could be separated—light, medium, and severe—but all had in common the tendency to multiple relapses which appear to be particularly frequent in the puerperium. The pulse rate follows the temperature, but becomes abnormally high only when serious pulmonary complications supervene, and usually does not exceed a frequency of 100–120, even with the highest temperatures.

The differentiation between influenza and puerperal fever is not always possible when the local manifestations are not pronounced, and the two affections, especially their milder forms, are easily confused. The occurrence of relapses and the relative slowness of the pulse are often of assistance in the diagnosis, but slight local symptoms, malodorous lochia, incomplete involution, and tenderness frequently appear in influenza and are not to be depended on, so that in the absence of bacteriological examinations the presence of an epidemic or pandemic is often the sole guide.—*Monatsschrift für Geburtshülfe und Gynäkologie.*

Cornu cutaneum Auris.—J. C. Lester reports a case of this rare affection. His patient was a man of fifty-eight years who presented an attachment to the upper half of the left ear of a horny excrescence, measuring in length a little over one and one-fourth inches and in width, at its base, one inch. The attachment included at its base the helix, fossa of the helix, and antihelix. In shape it resembled a pyramid, slightly twisted upon itself, with the apex turned toward the head. The distal end was found to be peculiarly square and blunt. This was due to the fact that a portion had been cut off by the patient with a pair of ordinary shears just five weeks prior to examination. According to the patient's testimony, since he excised the tip the growth had rapidly increased in size. A second attempt was made to excise another portion, but unsuccessfully, owing, as stated, to the hardness of the tumor. The growth at and near its base was soft and spongy, and its fleshy characteristics extended to about one-fourth inch from the point of attachment. Almost the entire cartilaginous portion of the ear, on further examination, was found to be practically ossified, being very rigid and having a bony feel, no amount of force used causing the slightest change in the conformation of this structure. The ear was loosely attached to the head and was otherwise normal. Immediate removal was advised, and was accomplished in an unexpected manner. The growth came away *en masse*. Hemorrhage was severe, necessitating the use of ligatures, and the immediate closure of the irregularly depressed wound by several sutures. The wound healed by granulation after a period of two weeks. The point of attachment was cauterized a few times by c. p. nitric acid, and the subsequent history of the case was uneventful.—*The Laryngoscope.*

The Pathology of Asthma.—G. N. Jack believes that many asthmatic attacks are due to intestinal indigestion and toxæmia with resulting abnormalities of the bodily fluids, especially the blood, lymph, and chyle. A prolonged treatment, lasting from two to three years and consisting of fresh animal and green vegetable diet, will often effect a cure. The urine and stools must be closely watched as a guide to dietetic procedures, and we may advantageously combine cold-water baths and regulated exercise with the dietetic regulations. Jack divides asthmatic blood conditions into three groups—asthmatic lymphocytosis, asthma due to an intestinal toxæmic leucocytosis, and asthma due to anæmia. Under the second heading he calls attention to the large percentage of eosinophile cells seen during an acute attack. He says that while it is as yet an undecided question as to the relation that the eosinophiles have to the other white blood corpuscles or their exact significance when occurring in either normal or abnormal numbers in the peripheral blood, nevertheless occurring as they do in such excessive numbers in a condition like this, in which the mortality of the leucocytes greatly exceeds their nativity, owing to a toxic and ill nourished condition of the blood, the said toxæmia originating from one of the breeding-places of the eosinophiles in the intestinal canal, would forcibly indicate that the leucocytes have an eosinophilic origin. This hypothesis would afford two rational explanations for their appearing in such excessive numbers in the blood of the asthmatic. First, that they had migrated into the blood substance to hasten the formation of new leucocytes; and, second, that they had been forced to abandon their normal breeding-places in the lymph tissue of the intestinal canal, from its toxic condition. Thus it will be seen that all of the pathological constituents found in this variety of asthmatic blood are directly due to the rapid completion of the life cycle of the leucocyte, with its consequent pathological representation of all of its life-cycle phases, as its origin, existence, death, and remains, which would be respectively represented by the eosinophiles, leucocytes, uric acid, and possibly Charcot-Leyden crystals.—*Buffalo Medical Journal.*

The Etiology of Adenoids.—In an analysis of three hundred and seven cases of adenoids, Macleod Yearsley says that the affection is essentially one of childhood, although it may persist to a very much later period of life. While it cannot be said to be hereditary, it often shows a distinct tendency to run in families, or, more correctly, to affect several members of the same family. The predominant causes are catarrhal inflammations and those of the exanthemata in which the upper air passages suffer most. The prevalence of adenoids in damp, cold countries is the outcome of this liability of the pharyngeal tonsil to become hypertrophied by catarrh.—*Treatment.*

An Unusually Large Polypus Presenting in the Pharynx.—A. V. Milholland reports the case of a woman in whose throat was a large tumor, occupying almost the entire pharyngeal cavity, pushing the velum palati forward, dependent from the rhino-pharynx, and reaching below the base of the tongue to the tip of the epiglottis. It was removed by cutting it through with a wire, and a nasal polypus was also extracted which formed part of the same growth. The seat of origin was distinctly located in the middle meatus, well up under the middle turbinate, at about the junction of its anterior and middle thirds.—*Maryland Medical Journal.*

A New Technique for the Reduction of Turbinal Hypertrophies.—The method is essentially a submucous cauterization effected by a special trocar with sharp-pointed obturator. With the obturator in position the trocar is thrust into the hypertrophied tissue for the necessary distance; the obturator is then withdrawn and replaced by a probe, on which is fused chromic acid or other cauterizing agent projecting beyond the end of the trocar. The whole is then withdrawn, and in this way the entire area to be cauterized is brought in contact with the acid. The operation is done under cocaine and followed by the use of a camphor-menthol spray. The advantages claimed are: 1. Simplicity of technique and the short time consumed in the performance of the operation. Any portion of the hypertrophied area along the entire line of the turbinal body, either anterior or posterior, can be reached by submucous cauterization with but one small point of incision. 2. Freedom from pain to the patient, either during or after the operation. Many patients object to the more formidable operations by galvano-cautery or turbinotomy, and the deleterious and nervous influence on the patient is sometimes considerable. 3. No untoward after-effects. There is no post-operative hemorrhage. The possibility of infection is reduced to a minimum. 4. No destruction of physiologically vital tissues. There is no formation of synechia, as all inflammatory exudate is submucous.—M. A. Goldstein, *The Laryngoscope.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM WOOD & CO., 51 Fifth Avenue.

New York, June 22, 1901.

SOME FURTHER REMARKS CONCERNING SUICIDE.

THE subject of suicide possesses a morbid interest for a large number of individuals. Indeed, as has been pointed out frequently, many cases of self-destruction have been shown to be due to the effect upon ill-balanced and emotional natures, of reading lurid accounts in the lay journals of such occurrences. Man is essentially an imitative animal, one of the legacies doubtless of his organization.

In consequence of this human weakness some people strongly deprecate investigations into the darker problems of life; especially are they opposed to such kind of researches being made public, declaring that by so doing the evil is intensified rather than diminished. There is, however, another and more sensible way of regarding the question. All are agreed that it would be of the greatest benefit to the race if means could be found to decrease criminality in general, of which suicide may be looked upon as a branch. The only sure method of accomplishing this object is by endeavoring to obtain as clear a comprehension of the matter as possible; for without this knowledge nothing practical can be accomplished. Taking this view of suicide, it will be understood that an examination of its phenomena is as necessary as other forms of criminal investigation, and will carry as great a sociological value.

Statistics reveal the fact that the act of taking one's own life is greatly on the increase in the various countries of the civilized world; and there also would seem to be no doubt that this is owing largely to advancing civilization. In the MEDICAL RECORD, October 20, 1900, some of the most probable causes of suicide were briefly touched upon; and the opinion was expressed that one of the most potent reasons for this modern weariness of life is the decadence of religious belief in all parts of the world. Of course it would be impossible to tabulate correctly the different causes of suicide, but in any such list compiled agnosticism, alcoholism, and misery due to want and the stress of life would occupy prominent positions.

Morselli, who has been the most voluminous writer and is perhaps the greatest authority on the subject, believed in a law of continued increase, and showed by a table that the percentage of increase from 1827 to 1852 was from one hundred to two hundred and thirty-eight. He also, referring to the fact that in the combined central and southwestern states of Germany the proportion of one hundred and fifty suicides in the million was given, sets forth the following ingenious theory: "The synthetic and most certain law which springs out of these facts is that in the centre of Europe, from the northeast of France to the eastern borders of Germany, a suicidigenous area exists where suicide reaches the maximum of its intensity, and around which it takes a decreasing ratio to the limits of the northern and southern states." Nevertheless, with all fitting respect to the opinions of so eminent an authority as Morselli, the importance of this supposititious law would appear to be greatly minimized when it is considered that Germans who emigrate are as prone to suicidal impulse as in their own country. This seems to point to racial idiosyncrasies as a dominating cause rather than to the effect of climate or to the neuropathic state of the system, which is said to impel those living under similar influences to self-destruction.

Reginald A. Skelton, writing in the *Nineteenth Century*, September, 1900, refuses to entertain the view that variations in the number of suicides in countries separated by purely artificial boundaries are owing to racial or climatic differences; he likewise brushes aside many other popularly assigned causes, and is tempted to think that emigration is a factor which has not been sufficiently considered in this connection.

In support of this argument, he cites the two countries of Europe having the least proclivity to suicide, Ireland and Italy, which also supply more emigrants than any other country in Europe; whereas Switzerland shows a large immigration and a high rate of suicide; the same rule applying to Belgium, where emigration is wellnigh counterbalanced by immigration.

However plausible this argument may appear, it does not, to our mind, upset the assumption that racial characteristics tend to suicide, for Mr. Skelton himself allows that valid objections can be brought against the emigration theory, and that after all it may be purely accidental. In truth, the complexity of the suicide problem is so great that with our present knowledge it would be absurd to assert that to any given factors can be assigned definite determining causes for the act.

As to locality, statistics plainly show that the suicide habit is much more prevalent among the inhabitants of large towns than among the dwellers in rural districts. The explanation of this is not far to seek. The "sons of the soil" lead a healthy outdoor existence. Their nerves are not unstrung and shattered by the wear and tear of the strenuous and ofttimes unhealthy life which must be led by the majority of the people of large cities, and the brains of the countrymen are not developed as are those of the townsmen. For example, in Berlin, according to Legoft, in 1877 there was an average of 309 suicides per million, against 141 per million in the rural districts of Prussia; in Rome a rate of 123 as against 30 in the country; and other large European cities, with the striking exception of London, exhibit similar figures. Accu-

rate statistics of suicide for the United States as a whole are not available; but assuredly, as in Europe, it is more frequent in the cities than in the country.

Dr. F. S. Crum, of East Orange, has recently written an article mainly dealing with the suicide question in Newark and in four other large American cities. Some most instructive facts are recorded in this contribution. The statistics of Newark, which are given from 1869–1900, indicate an increasing tendency to suicide in that city's population. The following table summarizes the suicide figures for Newark for a period of thirty years, and compares them with similar figures for four other large American cities:

Suicides for 100,000 of Population by Quinquennial Periods for Five Cities.

Period.	Newark.	New York.	Chicago.	Philadelphia.	San Francisco.
1871–75	11.8	14.1	12.6	7.3	30.0
1876–80	9.3	12.3	11.4	6.9	41.4
1881–85	12.3	14.9	13.7	8.9	31.8
1886–90	15.7	16.4	16.3	9.1	27.3
1891–95	15.9	19.4	23.7	10.0	34.7
1896–1900 ..	16.5	23.5	23.0	11.8	47.2

The most noteworthy points in this table are the steady progressive increase in suicide in all the above-mentioned cities, the exceedingly high rate in San Francisco, and the comparatively low rate in Philadelphia. Dr. Crum is of the opinion that the large number of cases of self-destruction perpetrated in the Pacific coast city may be attributed to a great extent to the cosmopolitan nature of its people, to the exceptional social and economic conditions which exist there, to the large excess of male over female inhabitants, and to its relatively small juvenile population.

From the mass of evidence collected it will be gathered that suicide is increasing *pari passu* with advanced civilization, and that the inhabitants of the large cities of this country are as susceptible to the suicidal impulse as are those of similar cities on the European continent.

While, as remarked before, no definite cause or causes can be singled out to account for this increase, it is at the same time judicious to give ear to every hypothesis calculated to aid in the elucidation of the difficulty. Dr. Haig, the well-known exponent of the ills resulting to health from the uric-acid diathesis, has recorded his belief that mental depression and suicide are due to errors of circulation in the nerve centres, these errors being due to excessive uric acid in the system, this excess being present from errors of diet. It might be worth the while of some investigator to follow this train of reasoning and to ascertain the kind and quantity of food consumed in the countries where suicide is most prevalent.

So far as remedies for the prevention or checking of suicide are concerned, it is to be feared that the suggestion of efficient measures to attain these ends would be impossible, at any rate until a clearer knowledge has been gained as to the cause. The fear of severe punishment following an attempted suicide might deter some, but it does not seem likely that any legislation which could be planned would be both effective and just. Perhaps, after all, the motives leading to self-destruction have their origin mainly in the pessimism produced by the existing social and economic conditions, and this will be eliminated only when society has become regenerated. If this be so, "we must possess our souls in patience" and await that happy time.

LIGATURE OF THE ABDOMINAL AORTA.

In the course of a very interesting paper published recently (*American Journal of the Medical Sciences*, September, 1900), Keen, of Philadelphia, reports a remarkable case of ligature of the abdominal aorta just below the diaphragm, for aneurism. In addition to the account of his own case, the author gives a review of the reported cases, all of which are of importance in the history of this grave operative procedure. Ligature of the aorta will never be a common operation for more reasons than one, but cases of aneurism in the iliac arteries are occasionally seen, and in some of these it seems that benefit and perhaps cure can be accomplished by shutting off the circulation in the aorta. It therefore becomes necessary to consider the feasibility and possible results of this operation, even though cases suitable for it will rarely be encountered. The case reported by Keen is remarkable in several ways. Two operations were done, the first of which disclosed an enormous retroperitoneal hæmatoma, to interfere with which was evidently very dangerous. When the wound from this operation was healed, gelatin injections were tried without success, and then the second operation, ending in the ligature of the aorta just below the diaphragm, was carried out. The original idea had been to introduce wire into the sac, but this did not seem advisable. The patient lived forty-eight days, and the autopsy showed that the ligature had cut through the walls of the aorta, so that hemorrhage had occurred.

There have been twelve other recorded instances of ligature of the abdominal aorta during the last century, and in all the patients have soon succumbed, though in several instances death has not occurred for a number of days or even weeks. From this we are able to see at once that the restoration of circulation in the legs and lower abdomen is not the difficulty which is most serious. In some of these recorded cases this restoration has been extraordinarily prompt, when we think of the apparent difficulties to be overcome. The technical difficulties and dangers of the operation in competent hands have rarely been described as very great, and shock has not seemed to have contributed much to the fatal results. The chief danger and the most unsatisfactory aspect of this question are made very clear by the study of the clinical history of the cases reported, both before and after the introduction of antisepsis. This danger is secondary hemorrhage. When suppuration was the rule in wounds, it is easy to understand how readily ligatures would slip and erosion of the walls of the vessels occur. In every instance except the ligature of the largest vessels these dangers have been removed, and we must therefore

look for some special reason for their persistence in such operations, and if possible find a way to safety.

As the arteries increase in size, the relative proportion of the yellow elastic tissue in their walls increases, until in the case of the greatest vessels it forms by far the largest part of the vessel wall. This elastic tissue is singularly inactive in its healing properties, and is poor in lymph vessels, through which its nutrition is maintained. The blood current, moreover, in the great vessels is very powerful; it cannot be held by the mere adhesion of the intima, and the muscular coat is too insignificant to cause any satisfactory contraction, so that we have to depend upon the unsatisfactory elastic tissue to form a barrier before the ligature is absorbed or displaced. With our present methods and ligature materials we have not been successful in getting proper closure of the largest arteries, and we may perhaps attribute our failure to this slowness of the elastic tissue in forming a safe cicatricial barrier to the impulse of the blood current, and to its tendency to undergo necrosis under pressure. The instrument suggested by Keen, in his paper, may prove valuable by bringing together broad areas of arterial wall by means of pressure which can be regulated, and by preventing too much pressure on the vessel wall where the arterial impulse is very strong—that is, just above the point of closure. This prevention of late hemorrhage seems to be the only thing necessary to insure success in some cases of aneurism of the largest vessels, and it seems as if this improvement in results ought to be attained. The question seems to depend upon the inactive physiological character of the walls of the great arteries, for which, so far, we seem not to have made due allowance.

THE PHYSICIANS' STRIKE IN GERMAN CITIES.

The physicians employed by certain medical bureaux in Leipsic and Munich are reported to have struck some weeks ago in a body. The cause of the strike was the paltry pay allowed by the associations, and failing to obtain better terms the physicians combined and formed an organization conducted upon similar principles to those of a trade union. That the medical men of Munich were fully justified in refusing to continue their work, the statement that the pay after an increase reached the generous amount of fifteen cents a case will afford sufficiently convincing evidence. It seems, however, that the Munich doctors were not dissatisfied with this rate of payment for ordinary cases, but contended that it was not a satisfactory remuneration for performing surgical operations, or for cases requiring long attendance as childbirth. The bureau held a contrary opinion, and in consequence the physicians declined one and all to work for it. In Leipsic the circumstances resembled those of Munich except that the bureau was willing to hear complaints from physicians in its employ, but refused to recognize the organization. The strike in Leipsic, therefore, was for the principle of unionism. It is declared that there have been faults upon both sides, and that the patients are not one whit better satisfied with the treatment accorded them by the physicians than are the physicians with the conduct of the bureau. But what can be expected from a professional man who is paid at less than the rate of a hod-carrier in this country?

The co-operative system is being pushed to absurd lengths on the European continent and even in Great Britain, and there have been ominous signs of late that the "thin edge of the wedge" is being inserted in this direction in the United States. Physicians have a perfect right to combine to avoid being imposed upon, and those of the German cities who have thus asserted themselves will undoubtedly have the sympathy of the medical fraternity in America.

News of the Week.

Inspection of the New York Quarantine Station.—The consulting board of the New York quarantine, consisting of Drs. Bryant, Derby, Janeway, Biggs, Polk, Girdner, Peabody, McLane, Kinnicutt, and Prudden, recently made a careful inspection of the station and the methods of administration. The opinion of the board as to the conduct of this most significant element in the public health systems of the country is indicated in the following expression of approval: "The consulting board expresses its gratification at the admirable condition of the quarantine station; congratulates Dr. Doty on his success in so fully promoting the welfare of the port with such careful consideration of the interests of commerce; and cordially approves his aims and plans for the administration of the quarantine during the coming season."

War on Mosquitos.—The Italian authorities, says *The Sun*, are preparing this year to continue their war upon mosquitos in the Campagna, so as to give further proof that malarial fever is not only spread but propagated by these insects. Experiments along this line have been made for two years, and they have proved that in nearly every case the railroad employees, who have been protected from mosquito bites, have escaped malarial fever. The constant susceptibility of the railroad workers to malarial fever has always crippled these transportation lines. Practically the entire force has had to be changed several times in a season. The first attack on these mosquitos began in 1899. Prof. Angelo Celli conducted it. He worked on two railroad lines, the Prenestina Cervara and the Ponteglara systems. He selected five cottages on the first line, occupied by workmen, and three on the second line. Every known precaution to protect the inmates was adopted, with the result that in the protected cottages only four out of the twenty-four persons inhabiting them were attacked by malaria; and these four did not follow out the professor's instructions. In one cottage the residents would adopt no precautions, with the result that twelve out of its fourteen inmates contracted the fever. The experiments upon other lines were equally successful. Of a certain ex-

periment Professor Celli says: "Of a whole community of persons, all subjected to the same conditions, those whom we defended from mosquitos have remained free from fever, while those left unprotected have nearly all been attacked. It is as if we had a book with its pages alternately white and black, the white pages corresponding to our protected houses and families, the black pages representing those unprotected."

The Rockefeller Institute for Medical Research was incorporated on June 13th with the Secretary of State at Albany. The purpose of the corporation is stated to be "medical research with special reference to the prevention and treatment of disease." The directors are: William H. Welch, of Baltimore; Simon Flexner, of Philadelphia; Theobald Smith, of Boston; T. Mitchell Prudden, L. Emmett Holt, Hermann W. Biggs, and C. A. Herter, of New York City.

A Municipal Sanatorium for Consumptives.—An appeal was made last week by representatives of various taxpayers' organizations in Manhattan and the Bronx to have the city establish outside of the city limits a public hospital for the care of consumptive poor. The Henry law, passed by the last legislature, gives authority to the city to establish such an institution, and Mayor Van Wyck and Controller Coler are now investigating the subject.

Testimonial to Dr. Briddon.—On Friday evening, June 14th, the Alumni Association of the Presbyterian Hospital of New York City, Dr. W. K. Simpson presiding, gave a complimentary dinner to Dr. Charles K. Briddon at the University Club, presenting him at the same time with a loving-cup and an illuminated parchment testimonial, signed by the members of the association, in commemoration of his service of twenty-five years as attending surgeon to the hospital. The presentation address was delivered by Dr. Ben. Hedges, of Plainfield, N. J. Responses were made by Dr. Briddon, by the members of the attending staff, and by each alumnus present, as the loving-cup was passed.

Rival Lupus Cures in London.—The surgeons at the London Skin Hospital have been experimenting for some time with the use of the Roentgen rays in the treatment of lupus vulgaris, and have claimed more or less good results. Recently an apparatus has been set up in the London Hospital, an entirely distinct institution, for the treatment of the same disease by concentrated electric light, after the Finsen method, and still better results are claimed for this. The Queen has given her patronage to the London Hospital experiments, and the public is consequently subscribing liberally to defray their great cost. Certain newspapers of the baser sort, however, have assumed that the surgeons of the London Skin Hospital are envious of the success of their colleagues, and will not see that both are animated solely by a desire to arrive at the truth, and they are publishing alleged interviews in which the partisans of one method are made to express opinions very unfavorable to the methods employed and statistics published by their supposed rivals.

Adulterated Milk.—Many dealers in this city have recently been arrested and fined $25 to $50 for having watered milk for sale in their shops. In addition to their fines they were warned that if they were convicted again on a similar charge they would be sent to the penitentiary.

The Harlem Medical Association.—At the annual meeting of this society, held on June 10th, the following officers were elected: *President*, Dr. Joseph E. Lumbard; *Vice-President*, Dr. Edmund L. Cocks; *Secretary*, Dr. William H. Lockett; *Treasurer*, Dr. William H. Stewart; *Trustees*, Drs. Montrose R. Richard, Henry W. Mooney, and Henry J. Wolf. The association contains about three hundred members.

St. John's Guild Seaside Hospital.—The Seaside Hospital of St. John's Guild, at New Dorp, S. I., was opened for patients a few days ago, and the same afternoon the trustees and officers of the Guild visited the institution to open formally the Lewis Memorial Cottage, erected last fall by Mrs. Frederic Elliott Lewis in memory of her son.

Surgeon-General Sternberg has started on a visit of inspection of the army medical corps in the Philippines, and during his absence Col. William H. Forwood will be in charge of the medical department headquarters at Washington. Dr. Forwood has for some time been in charge of the medical depot station at San Francisco.

Smallpox in this city seems not to have decreased appreciably with the advent of warmer weather, four new cases and seven deaths having been reported in one day this week. Almost every steamer arriving at this port from Naples brings one or more cases among her steerage passengers. These, of course, are detained at quarantine and do not go to swell the list of the New York cases. In Indiana smallpox is so prevalent and resists so obstinately all attempts to suppress it, that the State board of health is considering the advisability of general free vaccination as the only practical means of limiting the further spread of the disease.

The Status of Christian Scientists in Georgia.—Judge J. H. Lumpkin, of the superior court of Georgia, recently denied the application for a charter for "The Atlanta Institute of Christian Science," the effect of his decision being that Christian Scientists cannot treat diseases in the State of Georgia without having been regularly graduated in medicine or passed an examination before the medical examining-board, the same as other physicians. The object of the institute, as stated in the petition, was to treat and heal according to the principles of Christian Science, as found in the Bible, and also in "Science and Health, with Key to the Scriptures," by Rev. Mary Baker Eddy. Judge Lumpkin held that, according to the decision of a case in the supreme court of Nebraska, Christian Science is the practice of medicine, and that medicine in Georgia can be legally practised only by persons who have complied with the requirements of the existing State law. This law provides that no person shall practise medicine within the State of Georgia unless he

has been heretofore legally authorized so to do, or shall hereafter be so authorized by a diploma from an incorporated medical college, medical school, or university, or has, after attending one or more full terms at a regularly chartered medical college, been in the active practice of medicine since the year 1866, or who was by law authorized to practise medicine in 1866, or shall have been licensed by the medical board.

Sir William Hingston, of Montreal, is the recipient of many well-deserved honors. He was not long since knighted by the Queen. Recently he received a beautiful testimonial from his former hospital patients and colleagues; and now the Pope has bestowed upon him the Papal Cross.

A Successor to "Vratch."—It is announced by the publishers of *Vratch*, the leading Russian medical weekly, which is to be discontinued in accordance with the will of the late proprietor, that the journal will be continued under the name *Russki Vratch*. The editors will be Drs. Padvysotski, now editor of the *Russki Arkhiv Patologii*, etc., and Vladislavleff.

Association of American Medical Colleges.—At the annual meeting of this association in St. Paul, on June 3d, the following officers were elected: *President*, Dr. Victor C. Vaughan, of Ann Arbor; *First Vice-President*, Dr. William M. Rodman, of Philadelphia; *Second Vice-President*, Dr. H. Bert Ellis, of Los Angeles; *Secretary*, Dr. Bayard Holmes, of Chicago; *Judicial Council*, Dr. Thomas Hawkins, of Denver, Dr. E. C. Dudley, of Chicago, and Dr. W. J. Means, of Columbus, Ohio. There are seventy-five medical colleges in the association.

Christian Science in Jacksonville.—A man in Jacksonville suffering from typhoid fever was under medical treatment during the greater part of his illness, and was apparently progressing toward convalescence when his physician was discharged and a Christian Scientist was called in. The man died in four days after this change was made, and the physician formerly in charge signed the death certificate, stating that "the deceased had typhoid fever, and it is my belief that the patient died of neglect and the interference of a Christian Scientist, and that the patient would not have died had he taken the medicine prescribed." The health officer of the city will take the matter before the courts.

The National Health League is an association recently started here, having for its very legitimate object the promotion of public health. Whether the means proposed for the attainment of this object are equally commendable is a question to be decided according to the individual point of view. Among those means are the doing away with physicians and druggists and a return to the health-giving properties of nature. A meeting of the league was held here recently, and the various speakers recommended the discontinuance of vaccination, vivisection, drug-taking, and surgical operations, the living on raw food, the wearing of hygienic clothing, cooling the abdomen, whatever that may mean, Christian Science, and anti-imperialism. A chairman of one of the sections of the American Medical Association spoke in favor of the aims of the league, but said he feared the spirit of commercialism governing the medical profession and the drug business would prove to be too strong for the league to overcome.

A Centenarian Park Laborer.—Barney Morris, an employee in Prospect Park, Brooklyn, celebrated last week what he claimed to be the one hundred and ninth anniversary of his birth. He was born in Ireland and came to this country seventy-nine years ago.

Dr. Theodore Walser has been appointed sanitary superintendent for the Borough of Richmond, an office made vacant by the death of Dr. John L. Feeny two weeks ago. The salary attached to the office is $3,500 per annum. Dr. Walser is a graduate of the Jefferson Medical College in the class of 1851 and is one of the visiting staff of the S. R. Smith Infirmary.

The American Institute of Homœopathy was in annual session at Richfield Springs, N. Y., this week.

The Plague at Cape Town has, from the beginning of the epidemic up to June 19th, claimed 342 victims. The total number of cases in the same period has been 715.

The American Orthopædic Association.—At the meeting of this society held at Niagara Falls, May 11, 12, and 13, 1901, the following officers were elected: *President*, Dr. H. Augustus Wilson, Philadelphia; *First Vice-President*, Dr. William J. Taylor, Philadelphia; *Second Vice-President*, Dr. G. G. Davis, Philadelphia; *Secretary*, Dr. John Ridlon, Chicago; *Treasurer*, Dr. E. G. Brackett, Boston. Philadelphia was chosen as the place for the next meeting, to be held in May, 1902.

Dr. John H. Coughlin has been appointed visiting physician to the Gouverneur Hospital, New York City.

Dr. Fr. Neugebauer, of Warsaw, has been elected corresponding member of the Academy of Medicine of Paris.

Address in Medicine at Yale.—The annual address in medicine at New Haven will be delivered by Prof. Edmund B. Wilson, Ph.D., of Columbia University, at 12 o'clock on Tuesday, June 25th, in College Street Hall. The title of the address is "The Higher Claims of Minute Research in Biology and Medicine."

Proposed Slaughter of the Innocents.—A Denver despatch states that a prominent member of the Colorado State Medical Association introduced at the annual meeting of that society, held this week, a proposed legislative enactment providing that, on the application of the parents, imbecile children be painlessly put to death. The proposed law is too wishy-washy. The children should be killed, whether the parents consent or not, and the latter also had better be put out of the way lest they procreate other children of feeble intellect.

The Class of 1876 of the Department of Medicine of the University of Pennsylvania held its first annual banquet at the University Club, Philadelphia,

on Alumni Day, June 11th, and effected a permanent organization for the benefit of its Alma Mater. The following officers were elected: *President*, Charles A. Oliver; *Vice-President*, William H. Klapp; *Secretary*, Francis M. Perkins; *Treasurer*, Benjamin F. Baer; and an executive committee of twelve members who will meet at the call of the president.

Health Officer Charged with Neglect of Duty.—Dr. Obed L. Lusk, deputy sanitary superintendent for the Borough of Queens, was indicted by the grand jury on Wednesday of this week. The charge is of neglect of duty, in allowing a man with smallpox to remain in his home in a crowded tenement and in not removing the body until more than two days after his death. The grand jury severely criticised the conduct of the health officer in the borough, and demanded that the board of health should institute needed reforms.

Dr. D. Bryson Delavan has been appointed consulting surgeon in the department of laryngology, St. Luke's Hospital, New York, in place of Dr. George M. Lefferts, resigned.

Complaints against the Management of a Consumptives' Home.—The residents of the upper part of the city have made complaint to the municipal authorities that the managers of the Seton Hospital for patients suffering from tuberculosis do not keep the patients within the grounds of the institution, and that patients are a menace to the health of the neighborhood on account of their disregard of the rules regarding expectoration. The authorities say that the nuisance complained of is in violation of the rules of the hospital, which are that the patients must keep within the grounds.

The American Christian Hospital at Cæsarea.—This hospital, started in a very humble way fifteen years ago by the Rev. Dr. William S. Dodd, an American medical missionary, now occupies a specially erected three-story building with seventy beds. The board of trustees of the hospital was recently incorporated. At its first meeting, held in Albany, N. Y., Mr. Allison Dodd was elected president, Samuel T. Carter, Jr., vice-president, Charles E. Manierre, secretary, and James M. Spears, treasurer.

"Malarium."—A Bon Ami, La., contributor to a Philadelphia contemporary, in the course of an argument demolishing the mosquito doctrine of the spread of malaria, suggests that the protection afforded by mosquito netting is due to the exclusion of the early morning air by the latter. "If so," he says, "people living under netting may be freed from malaria, or, as I prefer to use the singular number, from malarium." He probably reserves the "plural number" to designate a double tertian.

In Favor of a Psycho-Physical Laboratory.—In addition to the American Medical Association, the State societies of Connecticut, Indiana, Kansas, Kentucky, Nebraska, and Texas have passed resolutions favoring the establishment of a psycho-physical laboratory in the Department of the Interior at Washington. It is hoped that similar resolutions will be passed by the other State societies when the matter is brought to their attention at the annual meetings.

An Investigation into the Relative Merits of Baking-Powders.—The *Boston Medical and Surgical Journal* says that the Massachusetts legislature has ordered the State board of health to make a thorough investigation of the healthfulness of baking-powders, employing such tests as will demonstrate whether or not any brands of baking-powder on sale in that State are prejudicial to health, or whether the introduction into food of any of them in small quantities, which ordinarily would be harmless, would, when taken by a person suffering from some digestive disorder, injure the health. The board of health is ordered to make such recommendations to the next general court as the result of this investigation shall in its opinion warrant.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending June 15, 1901. June 7th.—Assistant Surgeon G. M. Mayers appointed assistant surgeon from June 1st. June 8th.—Assistant Surgeon J. F. Murphy ordered to naval academy June 15th. June 9th.—Surgeon A. R. Wentworth detached from the *Solace* and ordered to the *Albany*. Surgeon H. N. T. Harris detached from the *Albany* and ordered to the *Monocacy*. Passed Assistant Surgeon S. G. Evans detached from the *Monocacy* and ordered to the *Solace*. June 11th.—Assistant Surgeon J. W. Backus ordered to the *Vermont* June 17th. Assistant Surgeon F. A. Asserson ordered to the naval hospital, New York, June 17th. Assistant Surgeon G. M. Mayers ordered to the Pensacola navy yard June 18th.

Obituary Notes.—Dr. Hugh Stockdell died at his home in Petersburg, Va., on May 23d. He was the son of a physician and was born in Petersburg in 1835. He studied medicine first at the University of Virginia, and later at the Jefferson Medical College in Philadelphia, receiving his degree from the latter in 1859. He served as surgeon in the Confederate Army during the civil war.

Dr. Robert J. Martin, of Augusta, Me., was drowned on June 16th. He was graduated from the New York University Medical School in 1887. He was a member of the State medical board, and during the Spanish war was surgeon to the Marine Artillery.

Dr. Maurice B. Perkins, professor of chemistry in Union College, died suddenly on June 18th, aged sixty-five years. He was born in New London, Conn., March 14, 1836. He studied chemistry in Germany, and on returning to this country in 1862 he was appointed assistant professor of chemistry at the College of Physicians and Surgeons in New York City, and in 1863 at the Lawrence Scientific School of Harvard. He was called to the chair of chemistry in Union College in 1865, and held the place up to the time of his death. Harvard University granted him the degree of A.M. and the Albany Medical College that of M.D. In 1886 he was appointed a member of the State board of health.

Progress of Medical Science.

Boston Medical and Surgical Journal, June 13, 1901.

Iodophilia.—Theodore Dunham coins this word to designate a reaction which occurs in the blood under certain pathological conditions. A spontaneously dried blood smear is treated with a solution made of three parts potassium iodide dissolved in one hundred parts of water; in this is dissolved one part of iodine. The resulting solution is thickened to a syrupy consistency by the addition of lumps of gum arabic and occasional shaking until they are dissolved. The blood smear is mounted in a drop of this syrup and a bit of filter paper placed at the edge of the cover glass to absorb the excess of fluid. The specimen is then ready for examination by an oil-immersion lens. When one or more leucocytes are stained a reddish-brown we have the condition called iodophilia, which is apparently always present in progressive suppurations and progressive pneumonias. It would therefore give aid in the diagnosis of doubtful cases.

Some Observations on Chronic Seminal Vesiculitis.—Arthur L. Chute and Richard F. O'Neil found sixty cases of this affection among five hundred and forty patients presenting various sorts of genito-urinary disease. The treatment which has given them the best results is massage of the vesicles and ducts and of the prostate per rectum. At first the time of massage should be very short, and at intervals of from five days to a week. Later the intervals are longer and the massage is more thoroughly done. In some cases of long duration, dilating with Oberlaender's or Kollmann's dilator seems to have a beneficial effect.

Medical News, June 15, 1901.

A Study of Some Complications and Sequelæ of Typhoid Fever.—H. A. Hare and H. R. M. Landis state that complications and sequelæ in typhoid fever do not seem very frequent among children. Among those noted are: Varicella, parotitis, bronchitis, pneumonia, hemorrhage, otitis media, furunculosis, periostitis, vomiting, subcutaneous abscesses, dysentery, cholecystitis, aphasia, caucrum oris, laryngeal stenosis, typhoidal meningitis, aud chorea. Typhoid fever is more and more fatal as life progresses. Chills may occur at the onset or at intervals throughout the attack. Diarrhœa is present in not more than half of the cases at the present time. Anorexia is generally present. A very important initial symptom is abdominal pain. Bronchitis has not infrequently been found at the onset. Headache is a very frequent nervous manifestation at the onset. Meningitis is often simulated in the beginning. Renal lesions at the onset are not usual.

The Treatment of Scarlatinal Nephritis.—Charles Gilmore Kerley believes that these cases should not be approached with fear and force, but with gentleness and therapeutic moderation. The first step in the management of a case of average severity should refer to the diet. Milk, broths, and thin gruels only should be given. The plain milk diet is not necessary. There should be two or three stools daily. Calomel gr. $\frac{1}{10}$ per hour till gr. i. has been given, every third or fourth day, with ʒ ii. to iv. of citrate of magnesia the intervening days if necessary. Aconite is a very useful drug. When aconite fails, hot air is used. Hot-water flushing of the colon is most valuable. For a child three years of age, 16 to 24 ounces of decinormal salt solution at 110° F. is introduced into the bowel by a rectal tube, which should be inserted at least ten inches. A pint to a pint and a half every six to eight hours answers best in the majority of cases.

American Medicine, June 15, 1901.

Pulsation of the Uvula in Aortic Insufficiency.—David Riesman states that investigation of this subject requires much caution, since muscular movements like retching or swallowing may simulate pulsatile phenomena. It is well to make the examination both with and without a tongue-depressor. There are two types of pulsation: a communicated movement connected with the throbbing of the carotids, and usually affecting the tonsils and faucial arches, and an independent movement, brought about by a systolic increase in the volume of the tissues. The phenomenon is of the same nature as the capillary pulse, and possesses no greater significance. Its existence adds only one more point to be looked for in the study of a case.

Excessive Eosinophilia in Trichinosis.—A. J. Patek reports the case of a young man aged twenty-one years, who ate pork sausage that was not thoroughly cooked. He soon thereafter suffered from gastro-intestinal disturbances and severe muscular pains. The sausage showed trichinæ. The blood was examined late in the progress of the disease and showed thirty per cent. of the leucocytes to be eosinophilous.

Journal of the American Medical Ass'n, June 15, 1901.

Round Ligament Ventrosuspension of the Uterus.—D. Tod Gilliam thus describes his operation: (1) Make a median abdominal section from three to four inches long between the umbilicus and the pubis. (2) Break up the adhesions and bring the fundus forward. After this the patient may be placed in the Trendelenburg position. (3) Seize the round ligament on one side and bring it to the opening. The ligament may be picked up between the thumb and finger, or by the aid of a bullet or blunt forceps. (4) Carry a silk thread under the ligament at a distance of about one and one-half inches from the uterus. This can be most conveniently doue with an aneurism needle, though an ordinary needle answers the purpose very nicely. This forms a loop under the ligament, which is not to be tied, but after withdrawal of the needle the two ends are brought out of the abdomen and secured in the bite of a snap forceps. (5) The other round ligament is secured in the same way and the ends of the thread are brought out of the abdomen and held in the bite of another snap forceps. (6) Catch up with a volsellum the fascia, muscle, and peritoneum at the margin of the incision and an inch or so from the lower angle of the same, and make traction. This pins the layers together, prevents retraction of the muscle, and facilitates the next step. (7) Thrust the perforating forceps (specially devised for the purpose) through into the peritoneal cavity and seize the thread which holds the round ligament. The perforation is made slantingly, the forceps entering the fascia one-half inch from the edge and emerging on the peritoneal surface from one-half to three-fourths of an inch farther from the edge. The handle of the forceps is next tilted outward, which everts the lip of the incision and brings into view that end of the forceps which is in the cavity. The jaws are opened and the thread is placed between them. (8) Remove the clamp forceps from the thread and withdraw the perforating forceps. This brings with it the thread, and the thread in turn brings the ligament through the perforated wound in the abdominal wall. (9) While the ligament is held taut fasten it into the wound. This is done by a catgut suture which is passed through its base including the tissues on either side, then back again where it is tied. The thread which held the ligament is cut close to the ligament on one side and withdrawn. This is to prevent infection by pulling through the ligament that portion of the thread which had been exposed. (10) Treat the opposite side in the same manner and close the median abdominal incision. The projecting free ends of the ligaments are gathered up en route by the ruuning catgut suture which closes the fascia and drawn to the middle line.

Surgical Shock.—W. H. German says the symptoms of shock are of two general kinds, those due to a dulling or blunting of the vital powers, or torpid shock, and those attributable to mental terror or disturbance aud called erethistic shock (typical cases are narrated). Permanent impairment of health occasionally follows ordinary uncomplicated shock. A predisposition to shock may exist in persons of sensitive, nervous condition, or in the subjects of organic disease, especially of the heart and kidneys. In those cases of sudden death formerly classed as secondary or delayed shock, an explanation may be found in pulmonary œdema, in renal congestion, in concealed hemorrhage, or in septic collapse from the sudden absorption of poisonous material from a large serous surface such as the peritoneum. Or it may be due to fatty embolism in the small arteries of the lungs and other organs. As to treatment in this class of cases, the measures suitable to true shock are of most value, as heat, opium, strychnine, digitalis, alcoholic stimulants, and intravenous infusion or hypodermoclysis of decinormal saline solution. When fracture or crushing injury of large bones has occurred, it is very important that the limb be immobilized as soon as possible, so that the freeing and absorption of fat cells may be prevented.

Variability of the Tubercle Bacillus.—C. Ramus concludes his article as follows: (1) Tubercle bacilli are not always so easy to demoustrate as is commonly believed, even though present in large numbers. (2) The fuchsin solutions, like those of other dyes, cannot at all times be absolutely depended upon. (3) Tubercle bacilli from different patients, and from the same patient at different times, will not invariably stain by one method. (4) The bacilli exhibiting these varying staining properties are genuine tubercle bacilli, and not other species of acid-resisting germs. (5) The staining variations probably depend on physical and chemical changes in the bacterial substance, instituted either by antitoxic action or by the products of associated organisms, or by a combination of both. (6) In the absence of demonstrable tubercle bacilli, when physical signs of tuberculosis exist, a prompt diagnosis of that disease should be confidently made in the interest of the patient, and no valuable time be lost in waiting for typical bacilli to appear.

The Relation Existing between Diseases of the Conjunctiva, Nose, and Throat.—H. H. Brown believes that not enough attention is paid to this subject in our text-books or in current teaching. Relatively speaking, conjunctivitis in all that the term implies embodies as large and perhaps a larger variety of manifestations than any other disease in the domain of ophthalmology. Mere mention of the classification of conjunctivitis found in our text-books to-day is sufficient to emphasize the above. There is an intimate anatomical association between the nerves, blood, and lymph channels of the parts mentioned, and diseased conditions in each require a careful search for causative factors existing in the others. We must bear in mind that in all special work we are not dealing with isolated tissues.

New York Medical Journal, June 15, 1901.

A Modified Urethral Dilator Handle.—By F. C. Valentine. The instrument is described and illustrated. The advantages claimed for it are thus summarized, it being premised that the improvement in the handle of the instrument consists essentially in having the dial at the top of the instrument and two heavy metal projections for the easy grasp of the operator's left thumb and index finger. The technique of the employment of this modification and its action in nowise differ from those of the Oberlaender and Kollmann dilator. (1) While being guided by the amount of resistance for each increase of dilatation, the dial is continually under the operator's eye, positively guarding against any excess of dilatation and making any change of position unnecessary. (2) Having no dial or shield at its sides, this modified dilator is more easily introduced and more easily held in position during its employment. (3) The dial, being beyond the patient's range of vision, offers him no inducement unnecessarily and even dangerously to increase the calibre of the instrument. (4) The improved mechanism of this dilator handle simplifies the construction of the instrument without increasing its cost.

Paramyoclonus Multiplex.—L. J. Morton gives the clinical history of a fatal case and also a description of another case now under his care. The latter patient, a young Irish woman, was much overworked in domestic duties, and in addition nursed a brother who died of pulmonary tuberculosis. Her twofold duties impaired her health very much, combined with the loss of her brother, to whom she was greatly attached. Within a few months of his demise a sister became ill of the same form of lung disease, and she attended her until she broke down and began to have these clonic spasms, which involved first the muscles of the right side of the body, viz., the muscles of the right arm and leg. The spasms then passed over to the muscles of the left arm and left leg, then to the muscles of the neck and lower face. For a time the muscle spasm in the legs was much greater than at present, and both limbs were feeble and she could not walk without assistance. The patient and her attendant stated that when she was alone and not observed the spasms were not so great as when she was trying to perform some task in the presence of observers.

Penetrating Wounds of the Abdomen.—By R. S. Fowler. The paper is a plea for early operation after injuries of the nature alluded to in the title. The main point is to decide whether or not the peritoneal cavity has been entered. If the existence of such entrance is determined, no time should be lost in making an exploratory incision.

Philadelphia Medical Journal, June 15, 1901.

The Topical Treatment of Focal and Jacksonian Epilepsy.—J. William White describes the following method: The affected centre is determined in advance and its relation to the cranium indicated by a mark upon the shaven scalp two days before the operation. The scalp is sterilized and re-sterilized; a horseshoe-shaped flap is raised and a half-inch button of bone removed with a small trephine. The dura is left intact. Thirty minims of a sterile two-per-cent. solution of eucaine is injected into the brain substance at the centre of the trephine opening, the needle's point being introduced about three-quarters of an inch. This is gradually withdrawn as the last ten minims of the solution are injected. The flap is replaced and the patient returned to bed. On that day and the following he should receive full doses of bromides. At intervals, determined by experience, the injection is repeated. The patient should be kept in bed at least four hours after each injection and should take bromides for from one to two days. The writer does not claim that his results are noticeably better than those which seem to have followed many other operative procedures. But he believes that there are possibilities of benefit by this line of treatment which justify him in placing it conservatively before the profession.

A Case of Abdominal Pregnancy.—Augustus C. Behle describes this case. The patient was twenty-eight years old, healthy and well nourished. The abdomen was uniformly enlarged. Striæ were found all over the abdomen and on the side. A tumor was noted which extended a hand's-breadth above the umbilicus. It was elastic, semisolid, and non-fluctuating. A hard, globular mass was made out in the right iliac fossa, which was smooth with the exception of a slight depression at one side. Above the umbilicus and toward the left an irregular mass resembling fœtal limbs was palpated. The rest of the tumor seemed somewhat vague and difficult to outline. Neither heart sounds nor placental souffle could be heard. The cervix was soft, round, and not shortened. The fundus could not be outlined definitely. Ectopic gestation was diagnosed. Operation was performed. The fœtus weighed six and one-half pounds. The head lay in the right iliac fossa, the dorsum toward the right. The patient made an uneventful recovery.

Specialism and Some of its Relations to the General Practice of Medicine.—Henry Wallace believes that the specialist should develop by years of general training. A general physician need not fear in these days that he will lose the confidence of his patient by referring him to a specialist when necessary. The public is too intelligent so to misjudge a conscientious physician. It is perfectly proper and possible for a medical man not only to be a pure specialist, but to practise a specialty while attending to a general practice.

The Lancet, June 8, 1901.

An Explanation of the Vulnerability of the Apices in Tuberculosis of the Lungs.—E. H. Colbeck and E. Pritchard conclude that the vulnerability of the apices of the lungs to tuberculosis is largely determined by an alteration in the shape of the chest in conjunction with misplacement and deficient musculature of the shoulder girdle. Woods Hutchinson, who has worked at the subject from the side of comparative morphology and pathology, expresses similar views. The importance of the alteration in the shape of the chest and of the abnormal condition of the shoulder girdle lies, according to their view of the matter, in the modification which these changes induce in the dynamical relations of the superior aperture of the thorax, whereby the movements of the apices become inverted in their relation to the normal respiratory rhythm. It is in the altered dynamical relations of the respiratory mechanics at the apex that they find the conditions which favor the lodgment of extraneous matter in the upper lobes of the lungs. The exact position of the site of deposit is determined largely by the distance the apex rises above the border of the first rib, inasmuch as it is this extra-thoracic portion of lung which is acted upon by the forces that give rise to the inverted movement. Since the apex rises from an inch to one and a half inches above the border of the first rib they conclude that the site of deposit will be situated from an inch to one and a half inches below the summit of the lung. This mechanical explanation of the vulnerability of the apices of the lungs to tuberculosis in the human subject is the more interesting by reason of the fact that the proclivity to tuberculous disease of the basal lobe of the lung in cattle is in all probability likewise due to mechanical causes. The practical bearing of the theory which they have advanced is the enormous importance of developing the muscles of the shoulder girdle with the object of "pulling the chest into shape," as Woods Hutchinson so ably and graphically puts it. To this end tree climbing, ball throwing, horizontal ladder and bar exercises—indeed, any muscular manœuvre which brings into play the great pectoral muscles should be sedulously and systematically carried out.

The Morbid Anatomy and Origin of the Various Presystolic Murmurs Heard at the Apex.—C. C. Gibbes says that the presystolic murmur has been proved to be present under the following circumstances: (1) Obstruction of the mitral orifice by sclerosis and adhesion of the cusps or by invagination of an auricular thrombus. (2) Dilatation of the mitral orifice with normal cusps and chordæ. (3) The mitral orifice of normal size but roughened margins. (4) Insufficiency of the aortic valves, with (*a*) normal mitral orifice and curtains; (*b*) dilated mitral orifice but normal cusps and chordæ; and (*c*) mitral orifice dilated and cusp and chordæ thickened. It is also found to be equally present when the regurgitant current is directed toward the anterior mitral cusp and when it is directed toward the septum, when the regurgitation is free and when it is limited, and when there is no aortic or mitral regurgitation at all, the only morbid condition common to all being dilatation and hypertrophy of the heart. The author feels justified in saying that the presystolic murmur cannot entirely arise from the auriculo-systolic blood-current as the supporters of the Gairdner theory claim. When writing on mitral stenosis he has contended that partial asynchronism of the ventricles caused the muscle tones to be audible during the diastolic period. If the cases are carefully studied when the presytolic murmur has been present in spite of the absence of mitral stenosis, it will be seen that

the two conditions common to the whole of them are: (1) hypertrophy of the heart muscle and therefore increased muscle tones; and (2) loss of compensation, producing partial asynchronism and thereby causing the muscle tones to be heard during the diastolic period, the intensity of the presystolic murmur varying in proportion to the amount of hypertrophy present.

Vitality after Severe Injury.—W. H. Clayton Greene relates the case of a man aged forty-nine years, who fell on to an area railing and impaled his left side and died in nine hours. Autopsy revealed the following injuries: There were a large irregular wound in the left hypochondriac region with fracture of the sixth, seventh, eighth, ninth, and tenth ribs, complete perforation of both walls of the stomach from before backward, perforation and laceration of the diaphragm, extensive collapse of the left lung, and perforation of the pericardium and of the left ventricle of the heart (this latter organ is now in the museum). The pleural cavity on the left side was full of blood and the stomach had been pushed right up through the opening in the diaphragm. There was a small amount of blood-stained fluid in the peritoneal cavity but very little in the pericardial cavity. Saline infusions had been used in the interval between injury and death, and to the benefit derived therefrom the author attributes the continuance of life for the period named.

An Early Experience Concerning the Therapeutic Virtues of Iodide of Potassium in Asthmatic Affections.—W. T. Gairdner quotes from a number of old letters which show that iodide was used in asthmatic affections by Barclay as early as 1850 or thereabouts.

British Medical Journal, June 8, 1901.

A Case of Cervical Rib.—T. E. Gordon reports this case. The patient was a farm laborer aged thirty-two years. His first symptom was an attack of pallor and numbness in the fingers of his right hand when he got up in the mornings. Finally, gangrene supervened. Examination had shown the presence of a cervical rib. This was removed. The cervical rib was in some way the cause of the arterial obliteration. The circulation through the subclavian was not obstructed. The cause of the arterial disease was probably, in part, the carrying of heavy weights. If the rib acted directly on the artery, it must have done so in some way upon which present pathology throws no light. It may have acted indirectly on the artery through the nerves. A nerve lesion is capable of causing gangrene, or structural changes in the blood-vessels. The absence of clear signs of a peripheral neuritis is a striking argument against the theory of nerve origin. This case resembles the local phenomena of Raynaud's disease, which is almost certainly a neurosis. The abnormal rib may have exerted its evil effects not at its distal but at its proximal extremity. Here the rib is in intimate relation with the seventh and eighth cervical and first dorsal nerves and with the inferior cervical sympathetic ganglion and its branches.

Note on the Pathology of Toxic Amblyopias.—J. Herbert Parsons states that since 1880 it has been known that the papillo-macular bundles of the optic nerves are degenerated in cases of tobacco amblyopia. The paralyzing effect of nicotine is obtained whether it is injected into the circulation or whether applied to the cells locally. The writer believes that the drug acts, not essentially upon the nerve cell, but upon the branchings (synapse) of the pre-ganglionic fibres around the cell. It is possible that there may be changes in the cell itself, but even the delicate Nissl method is not sufficiently delicate to show this. The action of nicotine may be reasonably supposed to be: (1) Vascular, causing vaso-constriction of the arterioles, which would explain the selection of the sparsely supplied macular region; (2) paralytic, upon the synapses either of the cone fibres, or of the inner granules, or of both.

A Case of Wandering Œdema.—Bernhard Smith describes this case. The patient, a man aged twenty-eight years, has irregular attacks of œdema which generally occur two each week, for three weeks, followed by a month's interval. The lesions are translucent, painless swellings. They generally involve the face, but have occurred on the ear, forearm, prepuce, etc. They start at night, and have completely faded by the following afternoon. The patient is of a sedentary, rather dyspeptic disposition, of regular habits. When in the tropics a few years ago, he never suffered from prickly heat or the bites of mosquitos.

The Effect of the Roentgen Rays in a Case of Chronic Carcinoma of the Breast.—Andrew Clark relates the remarkable improvement in a woman aged sixty years suffering from cancer of the breast, since the regular employment of the Roentgen rays, which has been done for some weeks. The treatment has been continued five days a week, the surface being exposed to the rays for fifteen minutes at a time. The induration has gradually been getting less and the patient has but little pain. The glands in the axilla are smaller, and her general condition is improving.

Cinnamon in Influenza.—Joseph Carne Ross is convinced that if influenza is treated with cinnamon within twenty hours from the appearance of its first symptoms, the patient will be able to return to his usual work within three or four days. The earlier the treatment is begun, the better will be the results. A delay of over twenty-four hours renders the treatment inefficacious. The cinnamon is in tablet form, and two should be taken every half-hour for the first two or three hours, and after that two every hour till the temperature becomes normal.

Quinine as a Prophylactic to Influenza.—W. Habgood believes that the administration of small doses of quinine—gr. ii. each morning taken with breakfast—will protect the individual against the influenza poison. He has tried it in his own case with success, having previously suffered five attacks in four years.

The Sore Throat in Measles.—John Haddon reports several cases of measles, the first symptom of which was sore throat. The throat was covered with white patches and the typical body eruption appeared a few days later.

French Journals.

Tuberculosis of Mesenteric Ganglia.—G. Carrière, in speaking of the prognosis of this affection, states that it ought to be reserved as in all tuberculosis. Nevertheless, it is one of the most curable forms of the disease. So many serious complications are possible, such as breaking through into the peritoneum and causing generalized tuberculous peritonitis, that the patient has indeed the sword of Damocles always hanging over his head. The treatment should be hygienic, alimentary, and medicinal. All fatigue should be avoided. Climate should be equable. The diet ought to be most nutritious. Milk, eggs, butter, rare meat, purées of beans and peas are to be given. As to the medicinal treatment, cod-liver oil, and during the summer preparations with an iodine base, should be given.—*Le Nord Médical*, June 1, 1901.

Localized Analgesia by Cocaine.—J. V. Laborde concludes that the dose should be reduced to as small an amount as possible, for if the limit of local anæsthesia is passed, general effects are provoked by consequent absorption from a large amount. Experimental work seems to indicate that the medium dose for an adult is from 2 to 4 cgm. There is nothing to hinder a repeated injection if the first dose proves insufficient. The intra-muscular injection is comparatively more efficacious to produce the analgesic effect and to give relatively a little more local extension for the field of operation.—*La Tribune Médicale*, May 29, 1901.

Transverse Rupture of the Aorta.—M. Letulle has discovered at autopsy a rupture of the aorta at two different points. The subject was a woman aged seventy-two years, who died suddenly. One rupture was transverse, embracing almost the complete circumference of the aorta a few millimetres from the origin of the vessel; the second was of less extent, not taking in the whole thickness of the wall, and having determined the formation of a dissecting aneurism. The aorta was thin without apparent atheroma. —*La Presse Médicale*, May 15, 1901.

Deutsche med. Wochenschrift, May 30, 1901.

Cerebral Hemorrhage in Verrucose Endocarditis.—M. Simmonds believes that an important relationship exists between these two conditions, and details seven instances in which verrucose endocarditis terminated fatally owing to the occurrence of cerebral hemorrhage. The patients were mainly children or youthful individuals, in whom other vascular or renal disease was not present, and who were also free from luetic, alcoholic, or other toxic taint, so that the usual causes of apoplexy could be safely excluded. In some of the cases on autopsy it was possible to determine positively that the cardiac lesion was the cause of the hemorrhage, and in the others the connection appeared very probable, so that it seems justifiable to draw the inference that verrucose endocarditis is more frequently a cause of cerebral bleeding than is usually suspected. In two of the cases it was possible to demonstrate (Gram-Weigert stain) in the vascular wall, at the site of rupture, micrococci apparently identical with those found in the valvular vegetations, so that it is likely that a mycotic embolus lodges against the vessel wall and produces degenerative changes, which favor the development of the miliary aneurisms constantly found, and terminate in rupture and apoplexy. The diagnostic value of these observations may not be very great, since in most cases in which cerebral symptoms accompany endocarditis the numerical probabilities are overwhelmingly in favor of the existence of embolism, but if the presence of hemorrhage seems possible it should be

borne in mind that this condition may be a direct consequence of the cardiac lesion.

The Treatment of Contractures of the Knee.—L. Heusner has applied to the knee joint the principle of tendon transplantation which proved itself so useful in other regions. The preponderating strength of the flexors of the thigh makes contractures of the knee, which are very intractable and often painful as well as disabling, comparatively frequent, and the author thinks that his operation offers the best hope of success in a large number of cases. The muscles that are available for this purpose are the biceps externally, and internally the gracilis, sartorius, semimembranosus, and semitendinosus. Of these the semimembranosus and sartorius are least suitable owing to anatomical reasons, but the others do not present great difficulties to transplantation. The incisions through which the tendons are dissected out should be made ample and carried halfway up the thigh in order that the structures to be freed may be thoroughly liberated from surrounding parts, after which they are subcutaneously to be drawn into another incision in the patellar region through which they are sutured to the quadriceps tendon. The cases operated on gave excellent functional results, the pain being relieved and deformity corrected, though the most scrupulous asepsis is necessary to avoid infection, which, if it occurs, is likely to cause sloughing of the transplanted sinews and jeopardize the success of the operation.

Berliner klinische Wochenschrift, May 27, 1901.

The Functional Significance of the Pyramidal Tract.—M. Rothmann says that the older view that the pyramidal tracts afford the medium of communication between the cortical centres and the spinal segments probably needs a certain amount of revision. Experiments on animals in whom the pyramidal decussation has been destroyed showed that there must be other means of connection between the upper and lower regions of the cerebro-spinal axis, for dogs so operated were able after two days to run about as usual, and though at first a moderate degree of weakness and ataxia was manifested this may have been due to unintentional additional injury to adjoining bundles and is quite imperceptible after two to three weeks have passed. While it is true that, particularly in the case of the pyramidal tracts, results obtained from animals cannot be unreservedly transferred to man, observations on monkeys and also on human hemiplegics leave little doubt that the pyramids are not the only carriers of voluntary impulses. In general it may be stated that so far we are unable to limit any function to the pyramidal tracts alone, and that for the motor function a number of other fibre-bundles come into consideration, but neither can we deny that the pyramids have an important share in this office. The progressive increase in size of this tract as we trace it through successively higher species seems to indicate the gradual assumption of power by the cortical over the inferior centres, and it is possible that in the course of development it will wrest from accessory bundles this function, as has already been the case with other of the phylogenetically older tracts.

Albuminuria and Casts in Artificial Coprostasis.—P. S. Wallerstein offers experimental proof of the older observation that simple constipation, if protracted for several days, can cause the appearance of both casts and albumin in the urine. By simply occluding the anus of rabbits the author was able to secure absolute constipation without any complicating by-effects, with the result that within twenty-four hours albumin and casts in small numbers began to appear, increasing from day to day, until finally the casts (hyaline, granular, and epithelial) were present in great abundance, as well as degenerated epithelium and red blood cells, and the animals died on the fourth day. In dogs, although casts appeared in moderate numbers after the second day, albumin could never be detected. The microscopical examination of the kidneys removed from such animals indicates that the epithelial cells of the uriniferous tubules are the seat of the cast production.

Münchener med. Wochenschrift, May 28, 1901.

Prolapse of the Female Urethra.—Glaevecke reports a case coming under his own observation and then discusses what is known about the affection in general. The prolapse of the urethra is an ectropion of the mucosa alone, which is separated from the submucosa, leaving the deeper parts undisturbed. The entire circumference of the canal, or only either the right or left wall, may be involved, and the site of relaxation may be either in the upper or lower third. In size great variations are met with, the tumor ranging from pea to hen's egg size, while the exposed mucosa may be simply hyperæmic, œdematous, cornified, or ulcerating and necrotic. The causes most often adduced, such as cystitis, vesical calculus, sexual excess, and masturbation, do not constitute the only etiology of the affection, which is most probably simply a local manifestation of a general relaxation of all the tissue, since it most frequently occurs in either children or senile individuals, the subjects of some debilitating condition, and is only exceptionally observed in those enjoying vigorous health. Acute prolapse, sequent on sudden exertion, has been described, but usually some long-standing form of strain is present, chronic constipation, chronic bronchitis, etc. The symptoms depend largely on the degree of mechanical insult to which the exposed mucosa is subjected, as well as on the obstruction to the flow of urine caused by the pressure of the little tumor, whereby difficult and painful micturition is produced. The diagnosis is easy if the base of what often appears like a vaginal polyp is accurately located and the meatus urinarius found, though this latter is frequently hidden deep in some fold of mucous membrane. The prognosis is good. Acute cases are often relieved by instrumental reposition, with or without the use of astringents, while in chronic prolapse ablation, followed by interrupted catgut suture of the ring-shaped wound, is more satisfactory than are the various plans of chemical or actual cauterization that have been described, and which, like Emmet's button-hole operation, often leave disagreeable sequelæ behind.

Agnathia and the Accompanying Lingual Conditions.—Kuse reports in detail on the pathological findings in five specimens of agnathial monsters forming part of the collection of the Pathological Institute of Göttingen. His results may be summarized as follows: (1) In four cases of human agnathia remnants of inferior maxilla, varying in size, were found, a confirmation of Winckel's observations. In the fifth case, that of a lamb, the jaw was entirely absent. (2) In two cases, in addition to the degeneration of the lower maxillary arch, the hyoid arch was also defective and there was a sacculated dilatation of the pharynx. This was also present in the lamb, though in this monster the hyoid arch was complete, an evidence of the independence of these two formations of each other. (3) The copula of the hyoid bone, as well as the greater cornua and the larynx, were well developed in all the cases. (4) Winckel's theory, referring the deformity to pressure through amniotic bands, does not seem tenable, for simultaneous pronounced anomalies of internal organs point to an early disturbance of the entire rudimentary organism. (5) In all instances in which the hyoid bone was well developed the lingual growth was also foreshadowed, the evidence tending to show that it was only the posterior segment that was present, while the anterior lingual body was not found. In those cases presenting a defective hyoid lingual structure was not indicated. (6) The thyroid may be normally developed in spite of serious malformations of the pharynx and hyoid.

The Edinburgh Medical Journal, June, 1901.

The Treatment of the Cough in Pulmonary Consumption.—Arthur Latham would first determine the direct cause of the cough, *i.e.*, whether it be from reflex irritation, especially from sources other than the air passages, without any need for expectoration; from accumulated fluid, or from other conditions such as catarrh of the pharynx, tracheitis, laryngitis, bronchitis, etc. The patient must be placed as far as possible under ideal conditions, and never subjected to any sudden change of temperature, or to any source of irritation, reflex or other. Drugs should not be given until all other measures have failed, and then never without considering the question whether in treating the symptom we are not aggravating the disease. The author gives a number of prescriptions to be applied in various conditions. The cough which occurs in the morning and is accompanied by expectoration is useful, and must never be checked by a sedative, but may be aided by a warm drink.

A Case of Acute Tuberculosis.—Noel Dean Bardswell reports the case of a boy aged sixteen years suffering from acute tuberculosis. He was admitted to a sanatorium, although in apparently a hopeless condition. For five months his improvement was slow; then it became more pronounced, and after eleven months the disease was apparently arrested in one lung and much improved in the other. He then returned to his home in the slums, and at the end of three weeks was readmitted to the sanatorium in a collapsed condition and died. The post-mortem gave proof of the great amount of arrest and repair which had taken place in the lungs, and was of interest as showing how much tuberculous material may be lying quiescent embedded in fibrous tissue, and give little or no indication of its presence.

On Enlargement of the Spleen in Cancer of the Liver.—C. O. Hawthorne reports several cases which go to prove that, although enlargement of the spleen is not to be expected with cancer of the liver, yet occasionally cancerous tumors may be present in the spleen as well as in the liver; that malignant disease in the left lobe of the liver may

counterfeit a splenic enlargement; and that similar appearances may be presented by a cancerous growth either in the wall of the stomach, or originating in connection with a malignant ulcer which has penetrated the gastric wall.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

BIRMINGHAM INSTITUTE AND THE COLONIAL SECRETARY—ERASMUS WILSON LECTURES—INGLEBY LECTURE—CHOREA—TWO ANNUAL MEETINGS—OBITUARY.

LONDON, May 31, 1901.

THE Birmingham Consultation Institute is advertising for five specialists to take the place vacated by Dr. Irvine. Meantime the late consultant has been appointed an inspector of schools. This appointment led to a scene in the House of Commons, where attention was called to the fact that the general medical council had pronounced the charges against him proved, and ordered him to come up for judgment at the next session. The colonial secretary thereupon lost his temper, treated the matter as a personal attack on himself through his brother Arthur, denied that Dr. Irvine's conduct was under the consideration of the general medical council, and declared the charge against him was merely "breaking the rule of the professional trades union." It is a pity Mr. Chamberlain was not more accurately informed of the facts and thus saved from stating in the House the thing that is not. His brother Arthur knows well enough that Dr. Irvine's sentence was postponed to give him the opportunity of reconsidering his position in connection with Arthur's scheme of setting up a cheap consultation shop. It is quite possible the council may not excuse Dr. Irvine from appearing because he has been somehow pitched into an office under government. There are plenty of people who look upon this appointment as a piece of gross jobbery, and it looks "fishy," as others say. They think Arthur's recent lawsuit did not shed a very brilliant light on his doings, and regret that Joseph should have put another weapon into the hands of his enemies. He was not bound to mix himself up with Arthur's folly.

Sir W. Foster followed the colonial secretary and declined to treat the matter as a personal one, and declared it was a public scandal to appoint any one to a distinguished position in the public service while he was under remand by the judicial statutory body appointed to regulate his professional conduct. He was much interrupted by the excited House, which, though it loves a scene, was impatient, for it was just the dinner hour. Sir J. Goust declared in the usual way that the president had appointed the most fit person. Mr. Balfour closed the discussion, and the dinner hour was saved.

It remains now to be seen whether the medical council has dignity enough to resent the snub administered to it by the education department and endorsed by the government.

The Erasmus Wilson lectures at the Royal College of Surgeons were concluded on the 22d inst. The lecturer this year was Mr. Walter Edmunds; his subject, "The Pathology and Diseases of the Thyroid Gland." It is only ten years since Mr. James Berry lectured on goitre at the same college, his Hunterian course for 1891 being on the pathology and surgical treatment of that disease. But these ten years have seen considerable advances in our knowledge of the thyroid and its diseases, so that Mr. Edmunds had much to say that is to some extent new. The effects in animals of excision of the thyroid, with and without the parathyroids, and of the removal of a lobe or part of the thyroid proper, were first described, and Mr. Edmunds was able to confirm the results of previous observers. With respect to the condition of the eyes in dogs from which the thyroid had been removed, he only noticed a change in one. After some months the eyes seemed sunken and the palpebral fissures narrower. Experiments on rabbits to test this point proved there was a marked tendency to this narrowing, and if the animals eventually died from thyroid symptoms the eyes became very narrow. Further experiments were made to determine the effects of removing the parathyroids in dogs, rabbits, and monkeys. The general result as to the eyes appeared to be that excision of the thyroid and the parathyroids was followed by enophthalmos with narrowing of the palpebral fissures. Total removal of the parathyroids seemed to produce the same; so did excision of the thyroid proper, when it gave rise to symptoms. But some operations not fatal at the time, especially those in which the parathyroids were interfered with, were followed by exophthalmos with widening of the palpebral fissures. The same operation might be followed first by widening and later narrowing, but Mr. Edmunds had never met with the reverse—at least not as a permanency. These eye changes seem to support the suspicion that the parathyroids are involved in the pathology of Graves' disease. Interference with the innervation of the thyroid was next considered, and then the result of excess of the gland in the system which may be produced theoretically, either by grafting or by the administration of the gland. Grafting seems unsatisfactory, and no physiological conclusions can be drawn from experiments at present recorded, but the results of thyroid feeding have been carefully investigated, and the lecturer gave details of its effects on animals.

In the third lecture, concluding the course, Mr. Edmunds dealt with Graves' disease and the operative methods by which it has been treated. Incidentally he considered the occurrence of sudden death, which has sometimes immediately, or within a day or two, followed operations. Whatever the explanation, he thought these cases need not turn us wholly from the idea of operating. After full consideration of the fatal cases recorded, he concluded, in fact, that the lesson to be learned from them is not that operations should not be performed, but that they should be performed earlier.

Dr. W. J. Smyly went to Birmingham and delivered at the new university, on the 14th inst., the Ingleby lecture. He took for his subject "The Lower Uterine Segment and the Contraction Ring," thus launching himself on the troubled waters of two debatable questions, viz., What is that segment? What is that ring? Yet he made no attempt to grapple with them from an anatomical or physiological standpoint, but treated the subject from that of the practitioner; and none is more competent in that respect than the ex-master of the Rotunda. The nearest approach he made to a definition of the segment was to quote Bayer's words: "A portion of the uterus which before parturition resembles the body and after it the cervix." The lower segment is most frequently involved in rupture, and plays an important part in all cases of placenta prævia and prolapse of the funis, so that apart from the part it takes in strictly normal labor it deserves careful study. Dr. Smyly dealt with all these, and concluded that his task would be accomplished if he convinced his hearers of the importance of the lower segment and the contraction ring, and impressed them with the serious dangers of neglecting them.

Dr. L. Guthrie lately read a paper at the Medical Society on chorea, which he divided into sthenic and asthenic forms, with subvarieties and mixed forms. Some interesting facts were related and useful suggestions made. Fright, he said, was only another name for shock. The results are the same whether shock be physical or mental. The symptoms of chorea suggested a history of fright; those of articular rheumatism, exposure to bad weather; but he held that, if such connection were established, a history of fright in rheumatic fever and of chill in chorea would be equally forthcoming; but shock alone he regarded as only one of several factors. After a description of the several forms he came to treatment, on which two points call for remark. First he condemned the practice of pushing arsenic until constitutional symptoms are produced, as mischievous, useless, and unjustifiable. Many have been made extremely ill by this plan. Arsenic, he said, was no specific in poisonous doses, and he pointed out its dangers. But though opposed to its routine use in heroic doses, he found it useful in moderate amount in mild cases. This opinion will be widely indorsed. But the other point to which I have referred will surely excite more protests than were put forth at the meeting. This relates to alcohol. In asthenic chorea the treatment recommended by Dr. Guthrie he called recuperative and stimulant. In severe cases, he said, absolute rest in bed is essential with abundant nutritious diet. So far most will agree with him, but he went on to say "brandy should be freely given." Considering the patients are children, and the change in the convictions of the profession as to the use of alcohol which the last few years have witnessed, this is sufficiently startling. But Dr. Guthrie added that "four to six ounces in twenty-four hours are not too much for a child eight to ten years of age." He added that it is necessary to reduce the amount when improvement begins, "otherwise a low state of semi-stupor" occurs. Would you consider it too harsh a criticism to describe such treatment in plain language—as making children drunk? One speaker at the meeting asked whether such large doses of brandy would not be detrimental in other ways to the children, even if they did good in the disease. But he received no satisfactory assurances. How could he? The other speakers gave this point the go-by and directed their remarks to the other suggestions as to treatment contained in the paper, which were certainly more in accordance with modern views.

The annual oration of the Medical Society was delivered on the 20th by Mr. Richardson Cross, of Bristol. He devoted it to "Some Landmarks in the Progress of Medical Science." Naturally such a retrospect opened with a reference to the close of the Victorian era, the longest and most remarkable reign in our history, and a tribute to the late Queen, whose influence had always been directed to purify the life of the nation. Then the orator passed in review certain landmarks selected from the history of medicine, beginning with a reference to the early Egyptians and Babylonians, but rapidly passing on to Hippocrates and the Greeks. He mentioned the Jews, whose guiding principle he thought to be cleanliness. Greece was the motherland of rational medicine, and from Hippocrates to Harvey alone commended attention. Aristotle founded a school of anatomy at Alexandria, the focus of the intellectual life of the world. His plans and classification were copied two thousand years afterward by Cuvier. Galen (A.D. 131 to 202) was a Greek, but went to Rome, and subsequent Greek and Roman authors were mainly compilers from his writings. The orator mentioned other landmarks in the following centuries down to our own times. A vote of thanks was accorded by acclamation, and the meeting resolved itself into the *conversazione*.

The annual meeting of the Clinical Society was held on Friday last. The report was adopted and some changes were made in the rules. The president elected for the ensuing year is Mr. Howard Marsh.

Dr. J. D. Williams, gynæcologist to Cardiff Infirmary, died on the 21st inst. of typhoid fever, contracted during a continental holiday. He was only thirty-seven years old, but had achieved a very high reputation and is deeply lamented.

Dr. Robert Watkins, J.P., of Towcester, died on the 20th, aged seventy-eight years. His brother Edwin, also a doctor and retired naval surgeon, preceded him in death by a month.

LETTER FROM NEW ZEALAND.

(From Our Special Correspondent.)

DEATHS FROM CHLOROFORM—THE NEW SOUTH WALES REPORT ON THE PLAGUE.

AUCKLAND, May 6, 1901.

DEATHS from chloroform have been rather frequent here—that is, in New Zealand—of late. We had two last week. Inquests are of course held on all these cases, and the evidence is always of the same character—that every possible precaution was used, and that no skill, care, or attention would have prevented the fatal issue. It is rather curious that, during more than a quarter of a century that I have been practising in this colony, there has never been a single death from anæsthetics that could in any way be attributed to the ignorance or negligence of the anæsthetist! Considering that Lord Lister says that the majority of deaths from anæsthetics are caused by maladministration, this is rather remarkable.

A case occurred here last week, in which the post-mortem revealed a heart weighing fifteen ounces, dilatation, and fatty degeneration of the right side alone—there was no microscopical examination—and sudden death shortly after anæsthesia was produced. This inquest will be notable throughout the colony on account of the verdict, which was death "from misadventure." This reminds me of the stories of the pioneer days in your Western States, when a gentleman found dead on the side path with three or four bullets in him was declared by the coroner's jury to have "died from accidental lead poisoning."

But the most amazing part of the evidence was that of the gentleman who made the post-mortem, and who declared on oath that it would have been impossible to detect the existence of any disease before death, and that even if he had known the state of the heart he should not have hesitated to give chloroform! Comment is needless.

I have just received from the chief medical officer of the state of New South Wales a copy of the official report on the outbreak of bubonic plague which occurred there last year. The report is a most valuable and interesting one, a perfect model of an official report, without, I believe, one superfluous sentence in it. It contains a number of appendices, with much valuable information in them, and a number of diagrams and maps of Sydney and the suburbs drawn to a scale of four inches to the mile. These maps are beautifully executed, and do the greatest credit to the government printing-office in Sydney. They show by colored dots the exact locality where every one of the three hundred and three cases which constituted the epidemic occurred. The centre and business part of Sydney (the capital of the state) is situated near the water-side, and consists of irregular narrow streets and courts built after the fashion of the old European towns. All modern colonial towns are laid out on the American plan. It was in this old centre that the disease originated, and to it the greater part of the patients belonged either by occupation or residence. Only one defect I see on a hasty perusal of this report, and that is that we have no information as to the previous habits or health of the plague patients. I suppose the tyranny of a democracy would not allow the truth to be told, but I strongly suspect that it would be found that the vast majority of the patients were either of drunken habits or the children of drunkards. Many of the laboring class in Sydney are very heavy drinkers and eat enormous quantities of meat.

The following are the conclusions formulated in Dr. Ashburton Thompson's report: "(1) That the disease was not directly communicated from the sick to the well—in other words, was not 'catching.' (2) It was not communicated, in any important degree, at all events, from the sick to the well by mediate channels (clothes, household goods, merchandise, excreta). (3) The infection attached to localities, and spread to others adjoining and continuous with that in which it was first manifested. (4) It also spread in a fashion which betokens the possibility of its being transported mechanically from an existent focus to a considerable distance, and then initiating an independent focus. (5) In the buildings on any infected localities cases occurred irregularly, and showed no special proneness to occur in adjoining houses. (6) When the occurrence of one case among the inhabitants of a building showed that the infection was present in it, secondary cases rarely followed. Irregularity of incidence on houses was accompanied with irregularity of incidence on the inmates. (7) An epizoötic disease among rats preceded the first case which occurred in man. (8) This epizoötic disease was plague. (9) The area over which the epizoötic extended was practically co-extensive with that on which cases of plague in man were observed. (10) The epizoötic died out, as far as can be learned, at the same time as the epidemic ceased. (11) The epidemic was caused by communication of the infection from rats to man" (Report, p. 41).

Of course these conclusions apply only to Sydney and to the late epidemic. It is difficult to reconcile No. 2, for instance, with the universal fear, wherever plague is frequent or endemic, of touching anything that has belonged to the sick.

SPLASHING SOUND AND ATONY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue for May 25 I find the extract of an article from the *Berliner klin. Wochenschr.*, 1900, No 16, by Hans Elsner, Plätschergeräusch und Atonie (Splashing Sound and Atony), which extract gives an interpretation which is exactly the opposite of what the author of the original has said.

Elsner enumerates under which conditions the presence of the splashing found may be of pathognostic significance; he says that all authors unanimously are of the opinion that the topographic extent of the splashing sound may, under certain circumstances, be of value to judge the size and the position of the stomach, and again, "by establishing the extent of the splashing sound we are enabled to know approximately the position and anomalies of size of the stomach without being obliged to introduce a sound or to inflate the organ." He repeats again: "In regard to this point there exists no difference of opinion among the authors." At the conclusion of the article he emphasizes and has printed in large type: "Das Plätschergeräusch ist das constanteste Element der Enteroptose" (The splashing sound is the most constant element of enteroptosia).

In the extract in the MEDICAL RECORD we read: "H. Elsner is inclined to deprecate the value of this sign," but worse of all is that Elsner is represented as having said, "In gastroptosis absolutely no value attaches to the sign."

This extract reminds me of the reports which the medical journals brought of a paper which I had read before the American Gastro-Enterological Association on Atonia Gastrica; none of those journals gave a conception of the ideas I had presented.

A. ROSE.

NEW YORK.

[The abstract which our correspondent criticises conveys with absolute fidelity the meaning of the author. "H. Elsner is inclined to deprecate the value of this sign as an indication of gastric atony," for he says: "Es geht ferner aus unseren Fällen hervor, dass die Beziehungen zwischen Plätschergeräusch und motorischer Magenfunction nur sehr lockere sein können"; also, "Diese Fälle sprechen direkt gegen einen Zusammenhang von Plätschergeräusch und Atonie"; and, again, "Mit dem Tonus der Magenmuskulatur hat das Plätschergeräusch wenig oder gar nichts zu

thun." "Elsner is represented to have said, 'in gastroptosis absolutely no value attaches to the sign,'" because he said: "Bei Gastroptose hat das Plätschergeräusch niemals irgend welchen diagnostischen Werth." It would be interesting to learn how our esteemed correspondent would render these passages.—Ed.]

A STRANGE REQUEST.

To the Editor of the Medical Record.

Sir: Physicians are constantly meeting with curious cases, but the following is certainly a new one:

About 10 A.M. a young man called at my office and asked if I would inject a fluid (which he had in his pocket) into his bladder, at precisely one o'clock. He said he had some prostatic trouble and his doctor had given him the solution. He claimed to have just arrived in New York City. I refused, and asked him what the solution was, and he said it was a solution of glucose, but refused to say why he wanted it injected, stating that that was a private matter.

As an insurance examiner, glucose in the bladder is especially objectionable to me, so I advised the gentleman to be content without filling his bladder with glucose and showed him the door. Can you solve this mystery? If any one meets this man I would be obliged if he would let me hear from him.

William Moore, M.D.

320 Broadway, New York.

THE TRANSPORTATION OF MOSQUITOS IN BAGGAGE—A POSSIBLE EXPLANATION OF SOME EPIDEMICS OF OBSCURE ORIGIN.

To the Editor of the Medical Record.

Sir: Concerning the part played by the mosquito in the transmission of malarial fever and yellow fever, the following extract from a letter recently received is interesting and throws a side light on what sceptics call the difficulties of the doctrine. The writer of this letter (Dr. L. S. Harvey, U.S.A.) is a very intelligent, well-informed observer, and, I believe, entirely trustworthy:

"In regard to the possible carrying of infected mosquitos in baggage I had an experience last fall, which, while perhaps frequently observed, may be of interest at this time. A chest packed by me was left open for many days prior to my leaving Baracoa, in a room where there were many Culex mosquitos. The chest was closed, covered with a tightly fitting canvas cover and roped, and was not opened until my arrival in Washington some sixteen or seventeen days later. When the chest was opened, I distinctly saw at least three mosquitos of the well-known Baracoa variety fly out of the trunk. This may be a common experience, but since the mosquito theory has been promulgated, I have frequently thought how easy it would be to account for the outbreak of yellow fever at Fort Monroe by just such an experience as mine."

This observation is particularly interesting to those of us who have followed Major Reed's experiments in Havana and have become convinced that the mosquito, or rather one species of mosquito, is the usual and probably the only transmitter of yellow fever, at least in Cuba. It explains the breaking out of this disease in places not known to have been infected, and those rare cases occurring at points far removed from foci and attributed to tainted clothing or other fomites.

This observation also invites attention to our own experience of the physical endurance and resistance of mosquitos, especially in tropical or semi-tropical regions where they exhibit a nimbleness, swiftness, and longevity unknown in more northern climes. Thus, who has not slapped a mosquito with such force as to break one or more of its legs and bruise the abdomen, and, on lifting hand or finger, has not been surprised, and not a little provoked, to see the insect wriggle off and fly away? If, while a trunk is being packed and left open for that purpose, mosquitos light in it, it is not unlikely they may become caught between the folds or layers of clothing, and I doubt very much whether the usual amount of pressure put upon the contents of a trunk, when closing it, will destroy those which have found refuge in the many spaces existing in corners, inside the trays, or between garments.

It then clearly behooves all who live in or near foci of yellow fever, malarial fever, or filariasis to exercise some caution in packing trunks, chests, and boxes, so that the existence of these diseases may not constitute a sufficient reason for the continuation of the very troublesome and more or less destructive process of steam and formaldehyde disinfection.

Valery Havard, M.D.,
Surgeon U. S. Army.

Havana, June 10, 1901.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty-sixth Annual Meeting, Held in Chicago, May 30, 31, and June 1, 1901.

The society met in the Assembly Hall of the Fine Arts Building, under the presidency of Dr. Ely Van de Warker, of Syracuse, N. Y.

An address of welcome was delivered by Dr. Fernand Henrotin, of Chicago, which was responded to by the president.

Intraligamentous Cysts; their Diagnosis and Treatment, was the title of a paper by Dr. Chauncey D. Palmer, of Cincinnati, Ohio. This paper had special reference to the diagnosis and treatment of these tumors. Dr. Palmer spoke first of the classification of ovarian tumors in our text-books as being unsatisfactory. What was needed, he said, was a classification that was helpful in the way of diagnosis and treatment. He then spoke of oöphoritic, paroöphoritic, and parovarian cysts. The oöphoritic cysts were the hydrops folliculorum, and the unilocular and multilocular cysts. The oöphoritic had a Graafian follicular origin, and were not papillomatous, except very rarely. The paroöphoritic cysts started from the hilum of the ovary, and were papillomatous. All kinds of cysts, whether oöphoritic, paroöphoritic, or parovarian, might grow into the folds of the broad ligament and become intraligamentous. The paroöphoritic cyst was most apt to take on this special course of movement in its progressive development. The speaker then referred to the symptoms and signs before removal, which would enable the operator to differentiate intraligamentous cysts. All ovarian cysts of whatever kind, he said, should be removed by surgical procedures, the sooner the better. But the removal of intraligamentous cysts demanded the most correct knowledge of the parts and surroundings and superior skill. Intraligamentous cysts were, as a rule, easily peeled out of the broad ligaments. Enucleation, first suggested by Dr. Mynter, of Buffalo, could be done, but it ought to be attempted only when the attachments were superficial. Dr. Palmer referred to the danger of wounding the ureters or the uterine arteries, and earnestly advocated the advisability of completely exsecting the uterus as well as the appendages, when the cysts were bilateral and when they were deeply embedded within the surrounding textures. He spoke highly of irrigation of the peritoneal cavity with gallons of hot salt water after section, and also of a continuous peritoneal irrigation with hot sterilized water, used for hours or days, in many cases of post-operative septic peritonitis.

Improved Technique in the Surgical Treatment of Uterine Myomata.—By Dr. William H. Wathen, of Louisville, Ky. The perfection of technique in operations for the removal of uterine or pelvic myomata, the speaker said, was the result of the application in these operations of the variety of details suggested and practised by different surgeons, and operators no longer spoke of hysterectomy as an operation peculiar to any one, nor could they in many instances outline in advance the complete technique to be observed in an operation. The dangers during the operation were hemorrhage and injury to the bladder, ureters, or intestines, and if the surgeon was prepared to avoid these, and operate rapidly, there was hardly a condition that might not be successfully treated. Unless there was some contraindication, myomata not larger than a fœtal head might be easily removed per vaginam, and with the use of well-constructed forceps no successful operator would wound the bladder, the

intestines, or the ureter. Experience would aid in the selection of cases suitable for the vaginal method. The conditions most favorable for the vaginal method were a large pelvis, a large and easily dilated vagina, and a soft variety of tumor that could be easily morcellated. The author emphasized the value of well-constructed forceps in both the vaginal and suprapubic methods as a means of speedily and successfully completing the operation, and urged that, with few exceptions, no ligatures should be applied until the tumors were removed.

Painful Menstruation as a Factor in Determining the Character of Operations on the Uterine Appendages.—Dr. Philander A. Harris, of Paterson, N. J., divided dysmenorrhœa into primary, and acquired or secondary. The primary form included all cases in which dysmenorrhœa dated from the commencement of the menstrual function. Acquired or secondary dysmenorrhœa was not present at the onset of menstruation, but came into existence in the course of menstrual life, menstruation having been previously painless. Extra-uterine suppurations so commonly resulting from gonorrhœal infection of the uterus, and from the ordinary infections of childbirth and abortion, were of such frequent occurrence as quite to overshadow in importance all other causes of acquired dysmenorrhœa. Not all cases of suppuration in the uterus or tubes, however, caused painful menstruation. In a small percentage of such cases, even in the presence of extensive and long-continued suppuration, menstruation was painless. Tubal suppurations might, and usually did, cause painful menstruation before the development of ovarian abscess. This was proven by the fact that surgeons often had exsected both suppurated tubes, at the same time leaving both ovaries which appeared healthy, with the arrest of all pelvic pains and restoration to health, including a cure of the dysmenorrhœa. Ovarian abscess frequently developed from tubal suppuration, with the effect of increasing, modifying, or localizing not only intermenstrual pains, but also the pains of menstruation. Pronounced and persistent primary dysmenorrhœa would probably not be cured by the simple excision of diseased tubes, unless, as in certain rare instances, it was due to gonorrhœal infection prior to the beginning of menstruation, in which even it would be curable by excision of the tubes, vaginal incision, and drainage, or by the removal of the pyogenic sacs in the ovaries. By excision of a tube was meant its removal to the uterine mucosa by making an elliptical incision in the uterus about the tube and closing the chasm with sutures. In a very small percentage of cases of painful menstruation, the dysmenorrhœa was really a pelvic neuralgia, occurring at the menstrual period, with just enough coincident tenderness and pain over the sciatic or other nerve trunks to direct attention to its real character. Menstrual pelvic neuralgia was probably seldom complained of until menstruation was established, and should, therefore, be entered in the group of cases of acquired dysmenorrhœa. The author could not say that he had ever removed either one or both ovaries for the single purpose of curing dysmenorrhœa. He had excised ovaries which he felt were undergoing serious non-suppurating structural changes without reference to a previous dysmenorrhœa. In more doubtful cases, and in the absence of tubal suppurations, he would regard painful menstruation as a result of the suspected ovarian degeneration, and on that account would excise an ovary which possibly would have been allowed to remain, had the history shown an absence of ovarian pain or of dysmenorrhœa. In exsecting suppurating tubes, he believed that we should spare the apparently healthy ovaries in all cases of acquired dysmenorrhœa, for in such cases the function of menstruation was retained, which contributed so much to the moral and physical well-being of woman. If less radical measures of operation on the tubes than their excision could be relied on to terminate extra-uterine suppuration, then he would substitute such operations for the more mutilating excisions.

Status of Menstruation.—Dr. E. C. Gehrung, of St. Louis, Mo., said that menstruation was not, as had been supposed, a special function of the generative organs of woman, but only the perverted counterpart of the œstruation of the lower animals. This transformation into a monthly "hemorrhage" (menorrhagia) had generally been brought about by the necessities and results of the social, moral, and connubial life of mankind, as well as by the transmission by inheritance of certain debilities of the generative apparatus, and more especially by the erect position and its natural consequences. This fact being admitted, the profuseness and prolongation of the sanguineous loss were a proof that it was now a physiologico-pathological condition, predisposing to anæmia and disturbances of the nervous system. In the great majority of cases the quantity of blood lost during so-called normal menstruation was an unnecessary and, therefore, pathological waste of the very essence of life. It stood to reason that in all cases of depressed vitality this loss should be reduced as much as possible. The best means for controlling the waste was the vaginal (not uterine) tampon, applied *secundum artem*. Whenever curettage was not indicated or applicable, and when it had failed in producing the desired result, the tampon was the means indicated. Chronic and acute inflammations of the pelvic organs were contraindications. Unless the waste was restricted, tonics were useless because they simply increased the pressure and consequently the waste; but if given after the repression or simultaneously with it, they seemed to work wonders. The superstitions surrounding menstruation, as well as the misunderstanding of its true character by the medical profession as well as by the public, had caused a world of trouble and suffering by the neglect of the necessary advice and treatment.

The Age of First Menstruation in the United States.—Dr. G. J. Engelmann, of Boston, Mass., read a paper on this subject. The period of pubertal development, he stated, was an important epoch in girl-life, as the crest of one of the three great waves of functional activity, during which susceptibility to morbid influences was at its highest; much of woman's functional irregularity and suffering was due to neglect at this time; hence the pubertal period claimed the attention of the physician as a promising field for preventive gynæcology. To the physiologist and ethnologist the age of first menstruation in the United States, but little studied as yet, was of interest, as the extent of territory, with its variety of climate and the many races presented, offered exceptional advantages for the solution of still open problems as to the causes which influenced pubertal development, and which hastened or retarded the appearance of the menstrual flow. Over ten thousand observations as to the time of first menstruation of American-born women, many with reference to points never before investigated, here or elsewhere, gave him ample material for an authoritative solution of the questions involved. These observations, from his own practice and that of helpful friends, were many, and the identity of results obtained in far distant points, Montreal and New Orleans, St. Louis, Cincinnati, and Boston, vouched for their correctness. Furthermore, they were corroborated by all previous records, a total of six thousand, in such points as these might cover. The mean age of first menstruation in this country was 13.9, or 14 years, the same in the United States and Canada. Climatic differences in no wise influenced pubertal de-

velopment within the bounds of the North American continent; the American-born, be they of American (14.1), German (14.5), Irish (14.5), or French (13.6) parentage of the same class, attained puberty at the same age in Montreal, St. Louis, or Boston; the negro did not vary (14.05), whether in New Orleans or St. Louis. The greatest variation caused by the extremes of all influences was one year, from 13.5 in the girl of highest refinement and education to 14.5, which was the period for the American-born of the laboring classes, of German and Irish parentage; in other countries the difference between the extremes of social classes was from two to three years. Refinement, education, city life, nerve stimulation, determined precocious puberty; ignorance, poverty, and manual labor retarded; social status in itself meant very little; heredity and race had a slight determining influence. The American-born were more precocious than the women of other countries in the same zone; 14 was the age of puberty in the United States and Canada; 15.5 in the temperate zone of Europe. The native American was more precocious than the American-born of foreign parents, but the latter closely approximated the American of American parentage, even in the first generation. Racial characteristics faded rapidly away; the age of puberty in Germany was 15.5 to 16, in Ireland 15.3, and for the girl born in America of German or Irish parentage 14.5, in St. Louis as in Montreal. The Canadian-French were the only exception; the age of puberty was between 14 and 15 in their native land, and these alone of all races were more precocious than the American of the same class when born in this country; 13.7 was the mean age. Climate here had absolutely no influence; race very little; mentality, surroundings, education, and nerve stimulation stood out prominently in this country as the factors which determined precocity.

Cancer of the Uterine Fundus.—A paper with this title was read by Dr. J. M. Baldy, of Philadelphia, who stated that carcinoma in any part of the body was so well known for its virulence that there could be no surprise at the results of this disease recently reported from so many sources, when the uterus had been the organ attacked. It must be admitted that carcinomata of the same variety were intrinsically much the same as far as the disease itself was concerned, but the location of the disease rendered the practical aspect of the case widely different; and of all portions of the body in which it was safest for cancer to occur—if the word safe could be used in this connection at all—the fundus uteri was that portion. It was with the object of calling the attention of the profession to, and emphasizing as emphatically as possible, the wide practical difference between cancer of the cervix and cancer of the fundus, that this paper was presented. It had been said that practically all patients with cancer of the cervix eventually died of the disease; that practically all with cancers of the fundus remained well if operated upon. This statement was more generally true than one would suppose at first glance. It had been his own experience and that of other surgeons. Less than five per cent. of patients with cancer of the cervix were cured, no matter what line of treatment was followed. Twenty-four cases of cancer of the fundus had passed through his hands, a fairly large experience for one man. Of these, three were either too far advanced for operation or refused operative treatment. In the remaining twenty-one cases hysterectomy was performed by the vaginal method, the abdominal method, or the combined vagino-abdominal method. Two of the twenty-one patients died of the operation. Of the nineteen remaining patients, all were alive and well to-day, with two exceptions. One of these died of pneumonia seven years after operation. It was strongly suspected from the reports that the other one had recurrence. Making all allowances for mistakes and the general unreliability of statistics, the fact stood out strongly that about seventy-five per cent. of these patients were well and free from signs of cancer, as against five per cent. or less of cancer of the cervix.

The Status of Hysterectomy for Uterine Cancer.—By Dr. Cyrus A. Kirkley, of Toledo, Ohio. The paper was a plea for conservatism in the surgical treatment of uterine cancer, and contrasted its pathology and treatment of half a century ago with that of the present. While we had a revised nomenclature as to the varieties of uterine cancer, actual knowledge of the disease had not materially advanced. Old truths might have been made a little clearer as to its pathology, but its etiology was still unknown, and notwithstanding the advantages of asepsis and perfect operative technique, its treatment was still unsatisfactory. Due credit was given the advocates of vaginal hysterectomy for their skill and for whatever pathological fascination had made it too general; but it was maintained that the proper indications for it were too often disregarded and as often misunderstood. Instances were given pointing out this truth. With these discordant views as to the propriety of so serious an operation, the primary mortality of which was at least ten per cent., we might well hesitate in its adoption. The operation should be done at the early stage, when microscopical examination was necessary for a correct diagnosis. Most cases had passed the limits of a radical operation when the surgeon's aid was invoked. The paper took the view that adeno-carcinoma of the body of the uterus in its early stage, while yet localized, was the only form of cancer clearly indicating vaginal hysterectomy. Hysterectomy gave the best results in this variety of cancer. Dr. Cullen's and other tables were quoted showing average primary and remote results, but little was found in them to recommend vaginal hysterectomy as a general rule of practise. The paper then discussed the Rumpf-Ries-Clark operation, in which Dr. Pryor had reported in a total of ninety-eight cases by different operators a primary mortality of 11.2 per cent. When the disease had extended so far as to require it, little could be expected from any radical operation, because in most cases it was impossible to know whether all the diseased glands and infiltrated tissue had been removed. From the paper's viewpoint, the only indication for abdominal hysterectomy for cancer was when the disease was strictly confined to the cervix and body, or to the body alone. Electro-cauterization, as practised by Dr. Byrne, was given the preference over all the other methods of operating. It had not received the recognition it deserved. Dr. Byrne's skill in its application could be acquired only as in other operations. Freedom from danger and longer period of exemption were its strongest recommendations. An old table published by Dr. Byrne in 1889 was referred to, so that in comparison vaginal hysterectomy might have the advantage. In a total of three hundred and sixty-seven cases, there was not a single death from the operation. The position held by our fathers fifty years ago, that hysterectomy for cancer had its narrow limitations, that it should be done early if at all, and that only temporary relief could be hoped for, was just as true to-day. The parasitic theory of cancer might yet evolve something. One or two investigators were already agreed that they had found the parasite. The antitoxin of diphtheria was unknown a few years ago. Ovarian pregnancy, once generally considered impossible, had now been quite conclusively proven, and might we not as reasonably hope for a cure for cancer based upon the parasitic theory of its origin? Personally, the author was almost convinced of its truth, and had confidence that bacteriology would at least

point out the rational treatment for this terrible and incurable malady.

Prolapse and Procidentia of the Uterus.—By Dr. Henry T. Byford, of Chicago. Dr. Byford held that the essential feature of prolapse was the want of supporting-power of the pelvic connective tissue. To suture the uterus to the abdominal walls was to support the pelvic connective tissue by means of the uterus, and was wrong and inefficient. The best and most rational method was to draw up and attach the periuterine tissue and thus keep the uterus up by means of its natural supports. In addition to the ordinary operations for lacerations and relaxation at the vaginal outlet, the following method was proposed: First, the round ligaments were shortened intraperitoneally, making one large loop of each ligament, and then the loop was stitched to the parietal peritoneum a little above, and internal to, the internal inguinal ring, which was plainly marked by the entrance of the ligament. The uterus was now held in a nearly normal position, and the relationship of the other ligaments, as well as the effect of the work done upon them and upon the position of the uterus, could be gauged at every step. Second, the infundibulo-pelvic edges of the broad ligaments were sutured forward to the parietal peritoneum, external to the internal inguinal rings, as high as they could be drawn without much resistance. Then any available relaxed part of the broad ligament was sutured forward over or beside the round-ligament loops. Third, a suture was put through the base of each round ligament at its junction with the uterus, and it was sutured to the peritoneum over and beside the bladder. Fourth, the sacro-uterine ligaments were examined. If the peritoneum corresponding to their location was not drawn up and made somewhat taut by the new position of the uterus, or if the cervix sagged far forward toward the vaginal entrance, a short fold or tuck was made in it and it was sutured to the broad ligament beside the cervix, and perhaps lightly to the edge of the cervix, getting as broad a peritoneal apposition as possible. Fifth, the remains of the urachus were searched for at the lower end of the abdominal incision. A slit in the peritoneum was started an inch above the lower angle, and half an inch on either side, and extended downward and outward to the bladder wall. A transverse incision was made on either side, uniting the upper end of the slits to the abdominal incision. The peritoneum was separated between these slits, including as much connective tissue as possible, from the underlying fascia, and there would be formed a partly divided flap of connective tissue and peritoneum with the urachus near its centre. This was folded or twisted loosely into a sort of cord and attached to the rectus fascia at the edge of the incision, and high enough up to draw the bladder and anterior peritoneal wall well up. This suspended the bladder somewhat after the manner described by Dawson (*British Medical Journal*, July, 1898). The external sutures should catch hold of the newly formed vesical cord, or artificial urachus, and the lower one might even engage a few fibres of the vesical wall.

Panhysterokolpectomy, a New Prolapsus Operation, was the title of a paper read by Dr. George M. Edebohls, of New York. The very multiplicity of operations heretofore proposed for the cure of complete prolapsus of the uterus and vagina, he stated, was proof, if such were needed, that no operator of larger or longer experience was entirely and absolutely satisfied with the results of all his prolapsus operations. There was room, in the treatment of complete prolapse of the uterus and vagina, for an operation which, properly and successfully performed, would guarantee a certain and permanent cure of the prolapse. Such an operation was panhysterokolpectomy, the essentials of which consisted in complete removal of the uterus and vagina, followed by operative obliteration or columnization of the bed of the genital tract. The tubes and ovaries were not disturbed if they were healthy; if diseased, they were removed with the uterus and vagina. Obliteration and columnization of the bed of the removed uterus and vagina were effected by means of from seven to nine buried pursing sutures of chromicized catgut placed about 2 to 2.5 cm. apart, and running parallel to each other. Each suture gathered the raw surfaces from the periphery in circular fashion, and drew or pursed them together in the median line. It was buried by being pushed upward toward the abdomen, while the next suture was being tied beneath it. The effect of the completed operation was to build a solid pelvic floor 10 to 15 cm. in depth, and to establish broad apposition of the base of the bladder and the anterior surface of the rectum—conditions similar to those obtaining in the male pelvis. The patient was kept in bed for a week after operation. Recurrence of the prolapse was impossible after a correctly and successfully performed panhysterokolpectomy. The operation was indicated in the severest cases of total prolapse, and more especially when other operative procedures had been tried and failed. The interference with further marital relations must be explained, and accepted by the patient prior to operation. In the case of a married woman, the husband must also be consulted. Four patients had thus far been operated upon in this way by the author, all with perfectly satisfactory results.

Pus in Abdominal Operations.—By Dr. Hunter Robb, of Cleveland. As a result of the author's observations during the past seven years, he had become convinced that operators not infrequently erred in carrying out radical abdominal procedures when the patient's resistance was in such a lowered condition that she was very apt to succumb to the shock of the operation *per se*. Such a condition must always be given careful consideration in the decision for or against operative interference during an acute attack of a localized or more or less generalized pelvic peritonitis. Believing that this factor had a very important significance in influencing results, the speaker had made it a rule during the acute stage of a pelvic abscess to defer an operation as long as it seemed safe to do so. In the mean while, the patient was kept perfectly quiet on her back in bed, and heat in the form of flaxseed poultices or turpentine stupes was applied to the abdomen. In addition, a vaginal douche of a gallon of a warm one-per-cent. solution of carbolic acid, or a saturated boric-acid solution, was given twice daily. For nourishing the patient he depended upon nutritive injections entirely. Anodynes and heart stimulants were given if necessary. The micro-organisms that were most frequently met with in cases of suppurative disease of the tubes and ovaries were the staphylococcus pyogenes aureus, the streptococcus pyogenes, the gonococcus, and the colon bacillus. Other forms were occasionally met with, such as the tubercle bacillus and the proteus Zenkeri. After briefly discussing drainage in pus cases, the author gave the clinical and bacteriological analyses of seventy-two consecutive, unselected abdominal sections for suppurative diseases of the tubes and ovaries, with two deaths.

Removal of the Female Urinary Bladder for Malignant Disease.—A paper with this title was read by Dr. Matthew D. Mann, of Buffalo, N. Y., who stated that the operation for removal of the bladder had not received enough attention in this country, there being very few cases on record. Cancer of the bladder was rare, but was the commonest form of growth found in the bladder. The diagnosis could be made by the symptoms, the use of the cystoscope, palpation, and the examination of the urine. The treat-

ment might be removal through the urethra, through the vaginal septum, or by suprapubic cystotomy. The operations were the removal of the growth and its base; resection of part of the bladder; or cystectomy. Indications for total removal were multiple growths; return after removal; extensive involvement of the base; and extension of cancer of the cervix uteri into the bladder. The ureters needed no attention at the time of the operation, as by the removal of a portion of the anterior vaginal wall they would discharge into the vagina. If possible, the ureteric openings into the bladder should be left intact, but this would rarely be feasible. He did not believe in uretero-intestinal anastomosis. The vagina could be used as a receptacle for the urine, as was done by Pawlik. If this was done, there would be little danger of infection travelling to the kidneys, as the newly made bladder could be kept clean. The operation was done in the Trendelenburg position. The peritoneum over the bladder having been cut, the bladder was enucleated with the fingers, and the base, with the anterior vaginal wall still attached, was removed. The uterus was then removed, and the peritoneum closed over the floor of the pelvis. Mann reported two cases, in both of which the patients recovered from the operation, and he had collected from the literature fourteen cases more. He concluded that in certain malignant disease of the bladder, total extirpation was a justifiable operation, offering no serious difficulties to an experienced abdominal surgeon, and giving the patient a chance for a comfortable continued existence.

Total Extirpation of the Urinary Bladder.—This paper was read by Dr. J. Wesley Bovée, of Washington, D. C. He said the wonderful strides in operative surgery were typically represented in surgery of the urinary organs. He gave an epitome of the history of operative procedures in partial and complete removal of the bladder, and a digest of ninety-six cases which he had collected from the literature. He discussed the methods of disposal of the ureters, the indications and contraindications, and the results of all operations up to date, and presented the following conclusions: "1. Until a more satisfactory plan of disposal of the ureters is found, cystectomy should never be undertaken for conditions other than exstrophy, when partial extirpation of the organ is possible. Even a very small portion of the bladder into which the ureters may be debouched is practically free from danger of infection incident to bowel grafts, and, further, such disposition of the ureters is more easily executed. 2. For exstrophy of the bladder the Maydl and the Pozzi operations are quite satisfactory, though the danger of infection seems ever present. 3. Rectal graft of the ureter in its continuity and skin-grafting of this duct are highly dangerous. 4. Uretero-vaginostomy is practically free from ascending infection, though it gives far from perfect results. 5. Urethral graft of the ureter seems free from infection, but the constant dribbling of urine is but slightly ameliorated by the use of a urinal. 6. The Mauclaire-Gersuny operation is worthy of further application, inasmuch as it provides for both sphincter bladder and bowel." Accompanying the paper was a table of extirpations of the urinary bladder, comprising ninety-six cases.

Shock, from a Clinical Standpoint.—Dr. Eugene Boise, of Grand Rapids, Mich., read a paper with this title. The generally accepted idea, he maintained, that the pathology of shock was essentially a paresis of the vasomotor nerves, did not seem to be borne out by the clinical manifestations, when analyzed according to undisputed physiological facts. The basis of the theory of paresis was the thought that the extremely low arterial tension of shock was inconsistent with vasomotor stimulation, which, by causing arterial contraction, should give high tension. On the contrary, the symptoms of shock could, in reality, be explained only by the theory of extreme stimulation of the entire sympathetic system. Laboratory experiments had demonstrated that extreme stimulation of the cervical sympathetic would cause cardiac and arterial spasm with consequent low arterial tension by reason of incomplete diastolic relaxation of the heart. Post-mortem records showed that in fatal cases of shock the heart was found contracted and empty, even ruptured, showing a condition of extreme stimulation of the vasomotor system, rather than paresis. In shock, then, there was arterial and cardiac spasm, with consequent low tension. This caused the peculiar pallor and the condition of mental and physical lethargy. The perspiration of shock was caused by stimulation of the secretory nerves of the sweat glands, branches of the sympathetic system. Experiments had shown that the secretion of perspiration was independent of vascular conditions. The other clinical manifestations of shock could readily be explained by this theory of hyper-irritation of the entire sympathetic system, and only by this. Moreover, those remedies which were of benefit in shock were such as acted as sedatives to the vasomotor nerves. Nitrite of amyl and nitroglycerin were noted arterial relaxants, and yet they were very beneficial in shock. So, also, with strychnine. The opinion of operators of large experience was that to be of benefit it must be given in very large doses. And yet all therapeutists agreed that in such doses strychnine paralyzed the vasomotor centre and the intracardiac ganglia, and therefore was absolutely contraindicated if the vasomotor nerves were already paretic. So also with decinormal saline infusion. To derive the greatest benefit it should be used intravenously and at a temperature of 118° or 120°. Thus, when diluted by the mass of blood in the vena cava, the temperature was so reduced as to be sedative to the irritated cardiac and arterial nerves and muscles, and their spasmodic condition was relieved. Therefore, shock was essentially a hyper-irritation of the entire sympathetic system of nerves.

Resections and Exsections.—This paper was read by Dr. Fernand Henrotin, of Chicago. The author presented the salient points concerning the questions involved in resection of the ovaries and tubes, as there was still much doubt regarding the results obtained, and as to the proper methods to pursue. He considered the subject of resection and exsection under three heads: 1. Diseases involving the tubes. Salpingotomy and tubal resection were most undesirable operations, and only the most formally expressed desire for offspring on the part of the patient, after explanation of the uncertainty of results, would warrant their performance. Pyosalpinx always demanded exsection, and any tube materially damaged by any disease should be removed in its entirety. 2. Ovarian disease. All diseases of the ovaries, adjudged to be non-malignant, could be cured, and should be treated by resection of the diseased portions only. Recent ovarian abscess could be cured more quickly, more certainly, and with less danger by vaginal incision when this was practicable. When the abscess was of long standing, the sac should be removed, but even then some healthy ovarian tissue could almost invariably be preserved. 3. Chronic composite diseases. In most diseases of a composite nature in young women, when the tubes and ovaries were materially and equally involved, salpingectomy with ovarian resection was the most satisfactory operation, the uterus being retained. These three topics were taken up seriatim and discussed at great length. The author had performed at least two hundred and fifty operations which might be classified as salpingotomies, salpingectomies, and ovarian resections. He could safely state that forty per cent. might be termed delayed and par-

tial cures, or failures. Of this forty per cent., the heaviest proportion by far came from such as had had salpingotomy or tubal resection performed. The next most complaining class were those in which the ovaries alone had been resected, and the least suffering and the best health were found among those in whom the tubes when affected had been entirely exsected and the whole or portion of the ovaries removed. He had not had to reoperate more than five or six times. By salpingotomy the author meant opening into the lumen of the tube, and by tubal resection was meant the removal of a portion of a tube including the mucosa, and his statement presumed a material pathological alteration in the portion removed or incised. Under such conditions, he had no hesitation in stating that for every baby born there would be forty uncured or partially cured patients.

The Future of Gynæcology as a Surgical Specialty.—This was the title of the president's address, delivered by Dr. Van de Warker. Its general scope was given in an anecdote of a noted ovariotomist, who was invited by the president to contribute a paper to the section on obstetrics and gynæcology of the American Medical Association, at the session at which he presided as chairman. The ovariotomist declined on the ground that he was not a gynæcologist; that ovariotomy and hysterectomy and other abdominal operations were general surgical procedures, and were more in the line of the general surgeon than of the gynæcologist, and wound up his letter of refusal by predicting that the time was not far distant when these operations would be by general consent of the public in the hands of the all-round surgeon. The speaker asked the question if that time had not arrived. The public consulted the general surgeon as frequently as they did the special surgeon. A large proportion of the major pelvic operations were now made by men who were not specially recognized as gynæcologists. Surgery in general had made as marked advances in all directions as that which was at one time by common consent relegated to the specialist. The lay public had become more familiar with serious abdominal operations performed by the general surgeon, than those made by the gynæcologist. The great frequency of operations for appendicitis, on the gall bladder, for intestinal injuries, and for other intra-abdominal conditions, had educated the public to place as much reliance upon the surgeon at large in a field of surgery which at one time was regarded as the exclusive domain of the specialist. The same woman who would apply to the general surgeon for the removal of her ovaries would seek by chance the specialist for the performance of a genito-plastic operation. In her choice of a surgeon she was guided more by her senses than by her knowledge of her physiology. This evolution, for so the speaker regarded it since it involved the diffusion among the many of skill and knowledge which was at one time the property of a few, had already had a marked influence upon gynæcology as a surgical specialty, an influence which would have still wider effects in the future. This result was already to be detected in gynæcological literature. The old operation, ovariotomy, was but rarely seen in the title of a paper, and was relegated from the current journal to the pages of the text-books. The same might be said of the removal of the tubes and ovaries, the removal of pus sacs, Battie's and Tait's operations. Great international reputations were made in these fields, which was no longer possible. By making these operations common property, to be practised by all surgeons and all made on general surgical principles, they had to that extent ceased to be special operations confined to a few men. The influence of the gynæcological surgeon would, however, always be felt. To him as a man of last resort would always be left the question of methods and expediency. Total hysterectomy for cancer was yet on trial. It was already abandoned by able men, while others were hopeful of good results. Would the final verdict upon this question be given by the general or the special surgeon? The latter was trained in dialectics; he would bring to bear on the ultimate solution of such a problem qualities which the former could not possess, because he could not have universal knowledge and be the possessor of unlimited technique. All the great abdominal operations which were so eagerly exploited by the surgeon at large passed through this ordeal at the hand of the gynæcologist, and were turned out finished procedures both in expediency and method into other hands. The day was nearly passed when great gynæcological reputations could be made by the exploitation of a few operations. That belonged to the formative period of the art. A continent could never be discovered more than once, nor a new star give honor to more than one by its discovery in this alert age. But there was enough yet left for gynæcology to explore and add to the sum of its literature. The subject of pelvic dynamics was still left to research. We knew little of the subject of genital ptosis in women; our treatment of uterine displacements was rank empiricism. The physiology of the pelvic organs must at last be given its true value by the gynæcologist rather than by the physiologist in his laboratory, as it must be studied functionally rather than structurally. Questions of sociology, the insane, the criminal, social and industrial feminism, appealed to the gynæcologist with greater force than to other physicians. The question of coeducation into which eductors have rushed without heed of consequences must ultimately come before him for discussion. Many other fields of investigation, yet unexplored or only imperfectly known, still remained invitingly open. Gynæcology would always have its future, possibly brighter, more generally fraught with usefulness from the fact that its best minds were no longer concentrated upon matters purely mechanical, and which appealed to a comparatively few unfortunates, but because it would embrace in a broader scope all humanity. These were a few of the problems which the gynæcology of the future must meet, and with which men trained as the members of this society were ought to feel a profound interest. They not only studied the diseases peculiar to women, but they must also study social conditions that might tend to disease. There was no other department making such imperious demands upon its advocates as the gynæcology of the present, and they might be sure that it would not diminish in the future. There was nothing that contributed to the mental equipment of a man that the gynæcologist could do without. The ascendency of gynæcology as a surgical department would in no manner diminish because it shared its surgical triumphs with all who had the skill and knowledge to follow its lead; on the contrary, it would have a greater moral power when its advocates could find a field, broad and in close touch with humanity all about, beyond the limits of the operating-room. Would not the gynæcologists of France be doing a better service to their country and to science if they were to find the cause and conceive the remedy for the decadence of the birth rate, rather than bend their energies in finding a new way to perform an operation? If surgery had its limits, there were no limits to higher gynæcology. Either the word was badly constructed, or its meaning only half understood among those who attempted to limit it to surgical lines.

Indications for Cæsarean Section as Furnished by Pelvic Contractions.—By Dr. J. W. Williams, of Baltimore, Md. In 2,123 cases delivered in the obstetrical department of the Johns Hopkins Hospital, 278 (13.1 per cent.) had contracted pelves. The pelves were measured both externally and internally, and desig-

nated as contracted when the conjugata vera was 10 cm. or less in generally contracted, and 9.5 cm. or less in flat, pelves. Of the patients 941 were white and 1,182 black. Contracted pelves occurred in 6.91 per cent. of the former, and 18.1 per cent. of the latter; that is, in every fourteenth white and every sixth black woman. Of the 278 cases 199 ended spontaneously (71.58 per cent.). The number of spontaneous labors decreased with the increase in the pelvic contraction, as shown by the following table:

Conjugata vera	10–9 cm.,	77.28 per	. spontaneous.
"	8.9–8 "	61.54	"
"	7.9–7 "	33.33	"
"	6.9–5.5 "	0	"

The cases requiring operation were delivered by high forceps, version, symphyseotomy, Cæsarean section, craniotomy upon the dead child, or embryotomy, according to circumstances, giving a gross fœtal mortality of 12.96 per cent., and a gross maternal mortality of 2.88 per cent., which, by deducting the cases in which the death of the child or the mother was not due to the operators, gave a corrected mortality of 4.32 per cent. and 0.72 per cent. respectively. In view of the markedly improved results following Cæsarean section, the author stated, the indications for its performance should be widened. Thus we found that Zweifel, Olshausen, Reynolds, Bar, Charles, and Cragin had performed 162 operations with 5 deaths, a mortality of 3 per cent. He therefore believed that in uninfected cases the upper limit for the absolute indication for Cæsarean section should be advanced from 5.5 to 7 cm., and the relative indication from 7 or 7.5 to 8.5 for flat, and 9 cm. for generally contracted, pelves. With the absolute indication the operation should be done either at the end of pregnancy or at the onset of labor; but when the relative indication was present, the woman should be allowed to go into the second stage of labor, and have bearing-down pains for one hour, when, if the head did not show signs of moulding or descending, Cæsarean section should be performed, instead of forceps upon the movable head or version. So that at present Cæsarean section for the relative indication should compete with high forceps or version, instead of with craniotomy upon the living child, as in the past. On the other hand, if the patient was infected, or her surroundings were such that an aseptic operation could not be performed, high forceps or version should be attempted, followed by craniotomy in case one failed to deliver the child by their means, and Cæsarean section reserved for those cases in which an absolute indication was present on the part of the pelvis.

Circumstances which Render the Elective Section Justifiable in the Interests of the Child Alone.—This paper was read by Dr. Edward Reynolds, of Boston, in which the author summed up his experience and study of the subject in the following propositions:

"1. The Cæsarean section performed late in labor, or in the presence of infection of the uterus or other complicating constitutional conditions, has been shown, by the experience of almost every operator who has tried it, to have so high a mortality as to be totally unjustifiable when performed in the interest of the child alone.

"2. When a Cæsarean section is performed on a healthy woman, early in labor, and under otherwise favorable circumstances, for merely mechanical indications, it has, in skilled hands, no mortality other than the fractional percentage incidental to all considerable operations *per se*.

"3. The inconveniences and high morbidity rate of symphyseotomy render it distinctly inferior to the section as an operation of choice, but it is an operation which, as compared to craniotomy, or prolonged and forcible high forceps work without it, involves almost no increased risk to life. I therefore believe it to be the operation of choice in the somewhat limited number of neglected cases, *i.e.*, those for which the Cæsarean is ruled out, in which the pelvic contraction is within the range where the extraction of a living child without symphyseotomy is difficult or impossible, but after symphyseotomy is safe or easy.

"4. The induction of premature labor for contracted pelvis results in so high a fœtal mortality as to be unwarranted when placed in opposition to the performance of the Cæsarean section at the beginning of labor and in favorable cases."

After giving a brief justification of his position upon each of the above propositions, the author proceeded to discuss their application to practice. In conclusion, he urged his personal belief that no man was justified in performing Cæsarean section as a last resort late in labor, or upon infected or otherwise constitutionally ill women, for the sake of the child alone; but that he who attained to the fullest possible knowledge of his cases beforehand might do the section at the beginning of labor on healthy women, with even less risk to both mother and child than was involved in the performance of unusually difficult high forceps operations through contracted pelves. A statistical report of all the author's major operations accompanied the paper.

The Technique of Cæsarean Section.—By Dr. Matthew D. Mann, of Buffalo, N. Y. The author first discussed the relative merits of the Saenger and Porro operations. He concluded that there was no rivalry, but that each had its proper place. The classical operation should be done in all elective cases, when the woman was in good health, the operation was done in time, and all the conditions were favorable. The Porro operation should be done when the uterus was septic; when gonorrhœal infection was known to exist; when the uterus refused to contract; when there were large fibroids or ovarian tumors which could not be removed without injury to the uterus. Small fibroids usually disappeared after pregnancy. Other indications for the Porro operation were: disease of both ovaries; when the uterus was torn or ruptured in labor; in cancer of the cervix; when the patient was greatly reduced and bearing the operation badly; in osteomalacia and extreme degrees of atresia of the vagina. The uterus should not be removed simply to sterilize the woman, as this could be done, if thought best, by removal of the tubes. In this way the woman's sexuality was not destroyed. The question of sterilizing the woman was a hard one to decide, as ethical questions were involved. She might be sterilized in the interests of possible future offspring and of society, as well as to prevent possible future Cæsarean sections; but this only at her own request.

Technique of Cœliohysterotomy: a median incision is made into the abdomen and uterus, and the child and placenta are removed. The uterus is sutured with catgut. The Fritsch incision seems to be better if the placenta is in front. The uterine tourniquet is to be tightened when needed. A hypodermic injection of ergot is given and hot applications are made to the uterus, while the ether is withdrawn, to induce contractions. Careful toilet of the peritoneum follows.

Technique of Cœliohysterectomy: Same as before. Then the vessels are tied on each side of the uterus, and the uterus is removed, all but the cervix. The peritoneum is closed over the stump.

Vaginal Cæsarean Section: This is done for cancer of the cervix, and for rupture of the uterus. Few cases are on record.

Reports: Six operations have been done in Buffalo, by four operators, with the loss of one child. One

mother died, six weeks later, of carbolic-acid poisoning.

The Place of Symphyseotomy as Contrasted with Section.—This was the title of a paper by Dr. Charles Jewett, of New York. He presented the following conclusions:

"1. Symphyseotomy is still a useful operation within a very limited range of pelvic contraction.

"2. It is suited to conditions in which only very little additional pelvic space is required for delivery.

"3. It is a valuable recourse, therefore, in cases in which forceps unexpectedly proves inadequate.

"4. Axis-traction forceps, with the aid of posture, should always be tried before resort to symphyseotomy.

"5. Its results would be much improved by restricting it to pelves with a conjugate of not less than 7.5 cm. (three inches).

"6. Under equally favorable conditions its total mortality should be no greater than that of Cæsarean section.

"7. When the pelvic space permits, it should replace Cæsarean section in the presence of exhaustion.

"8. It may be elected primarily as an alternative of Cæsarean section, when the operator can be assured that the degree of obstruction is well within its safe limit. Here the choice of operation is largely a matter of individual preference.

"9. Within its proper field symphyseotomy is better than Cæsarean section for an operator of little experience in abdominal surgery."

The Relative Merits of Bipolar Version with Slow Extraction and Accouchement Forcé in the Treatment of Placenta Prævia; Report of Fourteen Cases.—A paper with this title was read by Dr. Henry D. Fry, of Washington, D. C. Podalic version, he stated, was discovered by Ambrose Paré in the sixteenth century. The method was practised and prompt delivery recommended in all cases of placenta prævia. Until the discovery by Braxton Hicks, in 1861, of the bipolar method of version, subsequent literature added little of value except the use of the tampon; rupturing of the membranes; and separation of the placental attachment as far as the finger could reach. The mortality of these methods of treatment was from twenty-five to fifty per cent. for the mother, and from fifty to eighty per cent. for the infants. The main cause of death was loss of blood during the dilatation of the os, and from laceration of the site of the placental attachment. The advantage of bipolar version was the ability to perform it successfully with very little dilatation and the consequently less loss of blood. Statistics based on the collection of a large number of cases treated after this method were wanting until the publication of the work of Lomer, Behm, and Hofmeier. The result was astonishing when reviewed in contrast with the mortality of the old method. Seventeen years had elapsed, and the brilliant results obtained by these operators had not popularized the treatment. Suppose, he said, we compare theoretically the bipolar method with accouchement forcé, and see if there exists any reason why the former might be considered safer in the hands of the inexperienced operator. In placenta prævia a fatal result was usually due to hemorrhage or sepsis. The hemorrhage was unavoidable and incident to dilatation of the os. Consequently the method requiring the least degree of dilatation necessary to perform version would naturally be expected to give the least hemorrhage. After dilatation was obtained in sufficient degree to permit the insertion of several fingers, further continuance of the process by manual means was likely to endanger the integrity of the soft parts. In other words, the artificial dilatation sufficient to perform bipolar version was comparatively safe, while that necessary for the insertion of the hand and internal version was dangerous. The rapid delivery of the infant in accouchement forcé added additional risk of rupture. There was one serious objection to bipolar version and slow extraction: the infantile mortality was greater. When interference was necessary before viability, or when the fœtus was dead, slow delivery was certainly indicated. If the life of the child be endangered during slow extraction, the obstetrician must decide between it and more rapid delivery with its increased maternal risks. The author gave briefly the histories of fourteen cases of placenta prævia which had come under his personal observation.

Scratch-Marks on Wax-Tipped Bougies in the Diagnosis of Ureteral and Renal Calculi.—Dr. Howard A. Kelly, of Baltimore, exhibited nine drawings made by Mr. Becker, showing scratch-markings made in wax-tipped bougies by calculi in the kidney and ureter; also pictures of the calculi and the bougies used were shown. A mixture of melted dental wax and olive oil, equal parts, was used to tip the renal catheters. This substance produced a smooth and highly polished surface, which on coming in contact with a stone was scratched or gouged in longitudinal striæ. The mucous membrane of the urinary tract could not possibly affect the waxed surface. In the method there were three sources of error: "1. Rubbing on the side of the speculum during the introduction of a catheter produces a flat facet, which in no way resembles a scratch-mark. 2. A to-and-fro movement in the effort to introduce the tip into the ureteral orifice may gouge the wax at the end of the speculum. This is avoided by keeping the end of the catheter free in the lumen of the speculum, skilfully carrying it into the ureter at the first effort. 3. Another source of error is drawing out the catheter and pulling it through the vulvar hairs; this is avoided by separating the labia and careful withdrawal." The evidences of stone in the urinary tract furnished by a catheter were as follows: 1. A sense of obstruction when the stone was struck by the tip of the instrument. 2. A free flow of urine, often turbid and purulent as soon as the catheter had passed the obstruction. 3. The injection of a weak solution of hydrochloric acid (15 c.c. of a one-half-per-cent. solution), withdrawn in ten minutes, had shown in one case calcium and magnesium phosphates, coming down subsequently in excess of the urine of the opposite kidney. 4. On the withdrawal of the catheter it might be held by the stone as if in the bite of a stricture. 5. The stone might yield a grating sensation as the catheter was withdrawn. 6. A bit of stone might be brought in the eye of the catheter, or be washed out by the injection of fluid into the kidney. 7. Bits of débris of the stone, little black specks, might be brought down by the urine, subsequent to the withdrawal of the catheter.

Surgical Treatment of Tuberculous Kidney.—Dr. Beverly MacMonagle, of San Francisco, read this paper. He drew the following conclusions: "1. All cases with vesical symptoms should be put through an exhaustive examination to exclude tuberculosis in the beginning of their symptoms. 2. This examination should embrace staining and animal inoculation with urine taken from each kidney. 3. In all cases of primary tuberculosis, the other kidney being healthy, nephro-ureterectomy is indicated and will give good results. 4. In advanced cases, involving one kidney and ureter, nephro-ureterectomy is indicated and preferable to nephrotomy. 5. In cases in which but one kidney is involved, early nephro-ureterectomy promises good results in a high percentage of cases."

Injuries to the Head in the New-Born.—By Dr. Andrew F. Currier, of New York. The importance of this class of injuries, the author stated, was measured not merely by the immediate damage to the skull or the soft parts of the head, but by the possibility of death

as a near or remote result, by the possibility of life-long defect or deformity, and especially by such detrimental effect upon the structure of the brain that development was arrested or prevented, the individual manifesting mental incompetence in any degree between slight backwardness and hopeless idiocy. Unfortunately, post-mortem examinations in fatal cases from this cause were seldom made, hence our pathological knowledge of the subject was incomplete. The free use of the obstetric forceps had, on the whole, produced favorable results, but it was equally true that its untimely, injudicious, or unskilful application had caused injury to many mothers and destroyed the lives of many children. The injuries in question might be received: (1) During natural labor; (2) during artificial or assisted labor. They might involve: (1) The parts external to the cranium. (2) the bones of the cranium; (3) the structures within the cranium. They might result: (1) In immediate death; (2) in death after a few days or months; (3) in recovery with lesions of the skull, and possibly such injury to the brain that mental development might be permanently retarded or wholly checked and paralyzed, rendering certain areas of the body useless or ineffective; (4) in recovery with disappearance of all evidence of the injuries received. The cause of these injuries during natural labor was usually a disproportion between the fœtal head and the maternal pelvis, or the sacro-vertebral angle might be too prominent, or the pelvis might be the seat of some variety of deformity. Rarely the injury might be transmitted through the pelvis of the mother to the fœtus during pregnancy or labor. Compression might affect a large head in a small pelvis, or a normal head might be retained too long in a normal pelvis. A skull thus compressed might resume its proper contour and show no outward evidence of injury, but long-continued compression often meant imbecility or idiocy. The effect of hemorrhage might be disastrous, the blood escaping through or into the scalp under the pericranium, or into the skull and its contents. Injuries in artificial labor might be unavoidable with the given conditions, or they might result from carelessness or ignorance. The high application of the forceps was responsible for many of the serious and fatal accidents to the fœtus. The forceps was also a frequent cause of fatal injury from compression, even when properly applied and skilfully used. Fissures and fractures were often present without outward evidence, and might be recovered from entirely, or might cause serious or fatal injury. After version or rotation of the head with the hand, serious injury might occur to the skull and brain. The injudicious use of ergot might result in fracture of the skull, the labor being precipitate or compression being excessive. These injuries involved:

1. The parts external to the cranium. The simplest form of those injuries was the caput succedaneum, which consisted in an engorgement of the tissues from interference with the circulation, followed by transudation of serum. This lesion passed away in a few days, and usually left no trace behind it. When the labor was severe, the blood-vessels might be ruptured, and the resulting tumor upon the scalp might contain blood. This might be absorbed, or it might result in suppuration and sloughing, with necrosis of the bone. The tumor might continue to develop during several days, and might be on the face, scalp, or any other presenting part. The eyes, ears, nose, or lips might be bruised or crushed, with resulting deformity, which might be permanent. Birth palsies from injury to the facial nerve were not infrequent, but their duration was usually transient.

2. The bones of the cranium. The bones might be indented, fissured, dislocated, or fractured. The frontal and parietal bones were most frequently involved. The bone might be indented to the extent of half an inch or more. Depressions which were produced slowly were not usually so serious as those which were produced quickly. The bone might be depressed alone, or fissured and fractured also. An injury to the bones might take place even when the labor was almost painless. Fractures might be simple, compound, single, multiple, comminuted, or depressed. Fracture might be caused by sudden and precipitated labor, the child being hurled into the world and dashed head-first upon the ground or any other hard substance. Fissures frequently started from a projecting ridge or boss. Indentations varied in their limits and their seriousness; they were often spoon-shaped, and might be caused by a projecting outgrowth in the pelvis, or a prominent sacral promontory along which the head was scraped.

3. Injuries within the cranium. These were the most serious of all the injuries to the head. If not immediately fatal, they might result in insanity, epilepsy, idiocy, or imbecility. Trismus and tetanus were often due to injuries received during labor. Hemorrhage within the cranium might be limited to this locality or it might extend into or through the scalp. Still-birth was very often the result of hemorrhage.

The results of these injuries might be: 1. Immediate death. This was often the result in long and severe labors, and often in those which were precipitate, the head being crushed during delivery or by contact with a hard body after birth. 2. Death after a few days or months. This occurred in the hopelessly injured, in the septic, in those whose vitality was defective, etc. 3. Recovery with permanent lesion of the skull or brain, or both, and with paralysis, convulsions, etc. All these conditions showed the importance of a careful examination of the head after birth, especially if the labor had been in any way unusual. 4. Recovery with disappearance of all evidence of the injuries received. The number of cases in this class was very large. It included all those in which slight injury was sustained, whether bruises, effusions of serum into the scalp, or even fissures, fractures, and depressions of simple character.

In regard to treatment, it was probable that life could very often be saved in cases in which injuries had been overlooked. In many other cases hopeless diseases might be averted by proper care and treatment at the beginning. The treatment should be instituted as soon as possible after birth, and if of a surgical character should be conducted along the same lines, and with the same attention to detail, which would be appropriate at any other period of life.

Tetanus following Cœliotomy: with a Report of Two Cases.—Dr. Henry C. Coe, of New York, contributed a paper on this subject. In his introductory remarks he stated that tetanus was such a rare complication of abdominal section that many operators of large experience had never had a case. Confident in the power of thorough asepsis to overcome the most virulent germs, we were apt to forget that there still remained some which resisted the ordinary methods of sterilization, and against which we seemed to be powerless to act, because as yet we did not understand their mode of development and the nidus most favorable for their growth. Statistics had shown that the disease was especially fatal after ovariotomy and hysterectomy. Tetanus was a rare cause of death after aseptic operations, as shown by reviews of various hospital records. Environment seemed to make little difference. In Bellevue Hospital, where conditions were apparently most favorable to the development of tetanus, this was almost unheard of, except as the result of wounds received before the patient was admitted. In the General Memorial Hospital, on the contrary, where the conditions were infinitely better, two fatal cases had

occurred since the hospital was opened (1887), and both in the service of the author. In both cases tetanus followed clean operations, after a normal convalescence, and under conditions which were quite inexplicable.

Case I.—Double salpingitis and cystic ovaries removed. The operation was perfectly simple. The convalescence was afebrile, though the patient was very nervous. Primary union of the wound ensued. The patient was out of bed in sixteen days. She complained of slight sore throat and trouble in swallowing. On the twenty-first day she was up and about. Slight stiffness of the neck was present. On the twenty-sixth day, slight spasm of the muscles of the jaw occurred. On the thirty-second day, the diagnosis of tetanus was made, and 25 c.c. of serum injected under the skin. The patient swallowed with some difficulty, but had no other symptoms. No rise of temperature was present and her general condition was good. On the thirty-fourth day she still took nourishment. An additional injection of serum was given. During the next two days general convulsions occurred, and death ensued on the thirty-sixth day.

Case II.—Pan-hysterectomy for fibroid uterus and diseased ovaries and tubes. The convalescence was absolutely normal until the ninth day, with primary union of the wound, when the patient had slight stiffness of the neck. On the tenth day she could not swallow. Serum (50 c.c.) was injected into a vein. General convulsions occurred during the night. A second intravenous injection was given. Death ensued on the eleventh day. In neither case were specific germs found in the blood or in the neighborhood of the wound.

In commenting on the cases, stress was laid on the difficulty of diagnosis, as both patients were hysterical and had no rise of temperature or other symptoms. Treatment was of no avail, though it was begun too late in the first case. The cases occurred eighteen months apart. No others had occurred in the hospital before or since. No cause was discovered, either in the technique or in the condition of patients before operation (both were in good health before and had been long under observation), or in the climatic conditions.

Questions for discussion were: (1) Could the development of the disease be prevented, and how? (2) Could the fatal result be averted by prompt resort to the use of anti-tetanus serum or other treatment? The answer to these questions in the class of cases under consideration was thus far a negative one. It seemed to be impossible to discover and act directly upon the focus of infection when it was within the abdomen.

Myomectomy during Pregnancy with Delivery at Full Term.—Dr. J. Duncan Emmet, of New York, read a paper with this title.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. S. C. Gordon, of Portland, Me.; *First Vice-President*, Dr. George M. Edebohls, of New York City; *Second Vice-President*, Dr. Edward Reynolds, of Boston; *Secretary*, Dr. J. Riddle Goffe, of New York City; *Treasurer*, Dr. J. Montgomery Baldy, of Philadelphia.

Atlantic City, N. J., was selected as the place for holding the next annual meeting.

Accidents after Adenoid Operations.—C. E. Holmes reports two cases in which the curette used for the removal of adenoids broke off just at the beginning of the sharpened portion of the loop. In one case the piece was removed without incident. In the other it was swallowed, but proper diet prevented any untoward consequences, and the piece was passed in the stools three days later.—*The Laryngoscope.*

New Instruments.

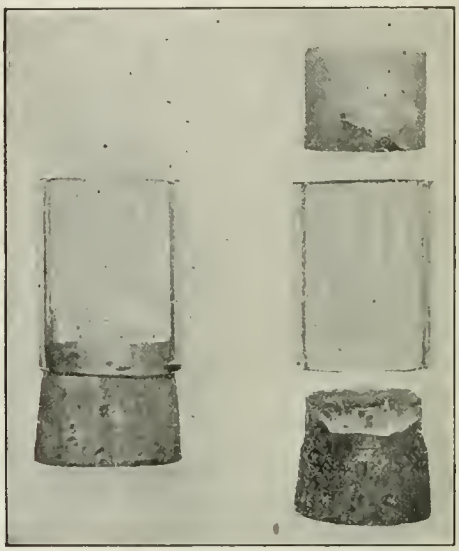
CUPS FOR PARAFFIN EMBEDDING.

By E. L. Oatman, M.D.,

Brooklyn, N. Y.

In the process of embedding tissues in paraffin, some difficulty and loss of time are experienced in pouring melted paraffin from the bath to the moulds, at the low temperature of 50° C., which is essential to the success of this method.

I now avoid this part of the technique entirely by using the same cup for heating and moulding. The cup is made by tightly corking one end of a thick



glass tube, about one and one-half inches in length and from one-half to one inch in diameter. The end of the cork which enters the tube should be covered with paper to prevent the paraffin adhering, while the other end should be weighted with lead to hold the cup upright while cooling. The tissue and paraffin are put in the cup and placed in the oven. After remaining the usual time the cup is removed and instantly placed in cold water. When the paraffin is solid, the cork is removed and the block pushed out. All the old paraffin should be carefully wiped from the inside of the tube, otherwise the next casting will not push out as easily as the first. Besides the saving of labor, this method gives a better cutting block than one which is slowly cooled.

82 Remsen Street, Brooklyn, N. Y.

The "X" Fever of the South from a Biological Standpoint.—Hayden A. West reports thirty-seven cases of a fever ushered in by not more than three days of discomfort. The temperature rose suddenly, and remained between 100.2° and 104° F. for from two to eight weeks. The thermal curve was irregular. The bowels were usually constipated, but nervous symptoms were absent. Examinations of the blood gave the following results: The hæmatozoon of malaria was never found. The Widal reaction was not positive at any period during the course of the fever. Typhoid bacilli were never isolated from stools or urine. No growth resulted from inoculations made with the patient's blood. The fever was evidently neither malaria nor typhoid, and it remains for a more refined technique and further research to bring out the cause of the "x" fever.—*The Southern Practitioner.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 15, 1901:

	Cases.	Deaths.
Tuberculosis	243	141
Typhoid fever	28	8
Scarlet fever	466	40
Measles	270	8
Diphtheria and croup	244	39
Smallpox	102	11
Chickenpox	81	0
Cerebro-spinal meningitis	0	4

History of Anopheles.—Nuttall and Shipley, writing in *The Journal of Hygiene*, say: "The first reference to Anopheles which we have found in the literature is that of Joblot (1754), of Paris, who describes the larva as rare, under the heading 'Description d'un Nouveau Poisson,' or 'Chenille Aquatique.' He gives a fairly good figure of the larva, considering the instruments he must have used. Fischer (1812–1813) figures 'Culex claviger,' the larva being those of Corethea. Meinert mentions that Gercke refers briefly to the larva in his 'Zur Metam. d. Dipt. Gatt. Dixa.' Brauer (1883) mistook the larva of Anopheles for that of Dixa, his figure being poor, while his enlarged figure of the head shows that he mistook the ventral for the dorsal aspect. Meinert (1886) gives fairly good figures of the larva of A. maculipennis and A. nigripes, the figures showing the whole larva, as also various parts studied in detail. Descriptions have been published more recently by Ficalbi (1899) and Giles (1900). The various stages in the evolution of A. maculipennis (syn., A. claviger, A. quadrimaculatus) have been described and figured by Grassi and by Howard (1900). It cannot be said that any of the descriptions hitherto published give a full and satisfactory account or entirely accurate figures showing the development of Anopheles. As to the representations which have appeared in medical literature, they have been either incomplete or very inaccurate."

Musical Dentistry.—The Paris correspondent of the London *Daily Telegraph* is quoted by the New York *Tribune* as follows: "Musical dentistry is the latest discovery here. Although your readers might believe the contrary, the idea is quite a serious one. It has been taken up by a well-known physician, who expounded it before the Paris Academy of Medicine, and it has thus received the sanction of high scientific authority. The method consists of drawing teeth to the sounds of sweet music. A usually trying operation becomes, it is stated, not only painless, but quite pleasant, when conducted in this way. The physician addressed the Academy meeting on behalf of a Paris dentist, who has already applied the musical method with success. The idea of the new process was first suggested by observation of patients under the influence of anæsthetics, the drug used being nitrogen peroxide in vapor. As is known, the incipient effect of the latter is to produce in nearly every case disagreeable, sometimes almost unbearable, sensations, resembling those experienced in nightmare. The dentist in question came to the conclusion that this preliminary ordeal of bad dreams at the beginning of the anæsthetic influence was caused by the perception of noises around by the mind when in a state of still partial consciousness. Why not soothe patients into the required condition of temporary oblivion by sweeter sounds? The dentist tried the experiment, and he and his patients were alike charmed with the result. The latter were as good as gold; the tooth-pulling operations, not being interfered with by the groans or contortions of the sufferers, were performed with the greatest ease, and on recovering consciousness all that patients remembered were bars of the "Lohengrin" overture, for example, still softly singing in their ears. The new method having been invented, nothing remained but to bring it to its greatest possible pitch of perfection. The obvious difficulties in the way of dentists keeping bands, solo singers, and choirs on the premises were avoided simply by means of powerful phonographs. Now the operator, whose new method has been revealed to the Academy of Medicine, regularly uses a machine of this kind. The patient puts the tube to his ears, the music is started, the gas administered, and shortly afterward the occupant of the once dreaded dental chair awakes from pleasant dreams to see the smiling surgeon showing him his tooth. Of course, a varied choice of musical selections can and, indeed, should be made to suit different temperaments and teeth. Without going into these particular questions, the physician spoke quite enthusiastically about the new process to the assembled academicians. He is eager to apply the musical method to surgical operations in general. He intends making experiments of his own in this direction, and he hoped that some of his hearers would do likewise."

The Diminishing Prevalence of Phthisis.—Mortality statistics collected in different countries seem to concur in giving evidence of a steady reduction in the number of deaths from consumption during the past half-century. It may be plausibly suspected that the whole of the apparent gain is not real, and that greater exactitude of diagnosis and a more precise use of the term "phthisis pulmonalis" may explain away some of it. Still, we may thankfully believe that a large part is real. We obtain support in that conclusion by the general impressions formed by intelligent old people, who, almost without exception, assure us they hear and see far less of "consumption" now than they did in the days of their youth. It is of great interest to determine the influences which have been at work in bringing about this result. It may be said at once that attention to the now so fashionable doctrine of contagion has had no material share in it, since, until the last few years, no sort of precautions on that score had been taken. It is possible, but, perhaps, not very probable, that the inspection of butcher's meat may have been influential in some slight degree. By far the most probable hypothesis is that the gain has accrued from the improvement in the general prosperity of the race, which the nineteenth century witnessed. During it mankind were, on the whole, prosperous, and in most civilized countries the houses, the clothing, and, above all, the food of the community were improved. To speak of England alone, those who can remember what it was sixty years ago assure us that the advance in the condition of the working classes has been very great. The food which is now obtained by all is more nutritious, more varied, and less exclusively vegetable than it formerly was. The clothes are better, and the houses are better. In spite of the fact that the age has witnessed the influx of population into cities and large towns and a partial abandonment of the country, the facilities for locomotion and the cultivation by both sexes of athletics and out-door pursuits have probably secured without diminution the advantages of fresh air. As regards the use of alcoholic beverages, the age has witnessed vast improvement. While there has been no diminution in the quantity taken, it has been spread over a larger number. Excess has become disgraceful, and is far less common than it was, while what may be called

the dietetic use has been maintained. Thus, then, we seem to come to the conclusion that the reduction in the prevalence of tuberculosis has been due to improvement in general stamina and advancement in the arts of civilized life.—*London Polyclinic.*

Liverpool School of Tropical Medicine.—The gratifying announcement has been made, says *The Medical Press*, that a prominent citizen of Glasgow has placed at the disposal of the Liverpool School of Tropical Medicine a sum of money sufficient to meet the cost of one year's exhaustive experiments in the pathology and prophylaxis of malarial fever. Scientific work in that direction has yielded such brilliant and practical results that there should be henceforth no lack of monetary support. There is no case in which funds are devoted to abstract scientific researches, which may or may not blossom and bring forth fruit for the good of mankind in a more or less distant future. The stamping out of malarial fever is an immediate benefit to the enormous number of our fellow-men who live in tropical and subtropical climates; yet that result is within the grasp of preventive medicine, thanks mainly to the classical investigations of Major Ross, who has recently received the honor of being made a fellow of the Royal Society. That step will meet with the cordial approval of those who are not inclined to the advisability of conferring the fellowship upon men whose only claim to distinction is some obscure physiological investigation of an interest limited to a small knot of advanced scientists in one particular branch of medical work. To relieve humanity of so terrible a scourge as malaria is to achieve the highest aim of philanthropic man. In a sense, it is comparable to Lister's feat.

Mr. Carnegie's Proposed Gift of Free University Education.—*The Lancet's* Scotch correspondent speaks as follows of Mr. Carnegie's enormous offer of $10,000,000 to pay the fees of students at Scotch universities: "After a period of calm, the Scottish universities have been startled by Mr. Carnegie's municipent proposal to throw their doors open to free education. When a man proposes to spend $10,000,000, in doing something, it is a mere platitude to enlarge on his generosity, so more need not be said on that point. So far as can be made out, the gift is not proposed as a gift to the universities, but to the public of Scotland, and the object is to place university education within reach of all Scottish youths of ability, free of cost so far as fees are concerned. This is not the place to examine critically the mouth of this gift-horse, but it may be said that there is a very wide and strong feeling that, while Mr. Carnegie's munificence is great and his intentions are admirable, he has not been well advised as to the direction in which higher education can be most benefited, or the means by which it can most advantageously be brought within the reach of able but impecunious youths. It is a pity if munificence on this scale should not be directed into suitable channels, there is so much to be done and so little money for the doing of it."

Hypnotism Extraordinary.—The Italians appear to be peculiarly susceptible to hypnotic suggestion under slight provocation, and failing any external influence they are prone to a kind of auto-hypnotism, which spreads until it assumes an epidemic form. We can recall an instance in which a whole village, or at any rate the feminine inhabitants thereof, became the subjects of maniacal excitement, which was appeased only by the despatch of a regiment of dragoons, whose presence had the desired effect of restoring peace to their troubled souls. Quite recently, a similar outbreak took place at a small village near Udine, where some twenty persons of both sexes and of all ages became hypnotized, after watching the contortions of a professional exorcist, and gave themselves up to more or less violent destructive antics. Although these manifestations are seen to the best advantages among the impressionable population of Southern Italy, it must not be forgotten that in a modified form they characterize crowds in all parts of the world. The influence of a crowd collectively on the individuals of which it is composed is a factor with which authorities have to reckon, and history shows that such a crowd will do things and commit deeds at which its units individually would be ashamed and even terrified. All commanding personages exert a similar influence over those who come within their sphere. Great preachers, and even mere demagogues, possess the power of galvanizing their audiences, dominating their intelligence, and subordinating their reasoning powers for the time being. There is no strict line of demarcation between this influence and that to which at a more advanced stage we apply the term hypnotism.—*Medical Press.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended June 15, 1901:

		Cases.	Deaths.
Smallpox—United States and Insular.			
Alaska, Douglas City	May 25th	5	
California, San Francisco	May 25th to June 1st	4	
District of Columbia, Washington	May 30th	1	
Illinois, Chicago	June 1st to 9th	6	
Indiana, Michigan City	June 3d to 10th	2	
South Bend	June 1st to 8th	1	
Kansas, Wichita	June 1st to 8th	7	1
Louisiana, New Orleans	June 1st to 9th	5	1
Shreveport	May 25th to June 1st	2	
Maine, Portland	June 1st to 8th	1	
Maryland, Baltimore	June 1st to 8th	1	
Massachusetts, Boston	June 1st to 8th	1	
Fall River	June 1st to 8th	1	
Marlboro	June 1st to 5th	1	
New Bedford	June 1st to 8th	27	1
Somerville	June 1st to 8th	1	
Michigan, Detroit	June 1st to 8th	33	
West Bay City	June 1st to 8th	1	
Minnesota, Winona	June 1st to 8th	1	
St. Louis	May 26th to June 2d	32	
N. Hampshire, Manchester	June 1st to 8th	4	
New York, New York	June 1st to 8th	86	16
Ohio, Cincinnati	May 31st to June 7th	5	
Cleveland	June 1st to 8th	30	
Toledo	June 1st to 8th	1	
Pennsylvania, Lebanon	June 1st to 8th	1	
Philadelphia	June 1st to 8th	..	1
Pittsburg	June 1st to 8th	5	
Rhode Island, Providence	June 1st to 8th	1	1
Utah, Ogden	May 1st to 31st	11	
Salt Lake City	June 1st to 8th	4	
Washington, Tacoma	May 26th to June 2d	1	
Wisconsin, Green Bay	June 2d to 9th	2	
Philippines, Manila	April 13th to 20th	9	
Porto Rico, San Juan	May 10th	8*	

* Extinct on island.

Smallpox—Foreign.			
Austria, Prague	May 18th to 25th	3	
Belgium, Antwerp	May 18th to 25th	3	1
Brazil, Pernambuco	April 1st to 15th	..	27
China, Hong-Kong	April 22d to 27th	7	5
Colombia, Panama	May 27th to June 3d	5	1
France, Paris	May 18th to 25th	..	15
Great Britain, Glasgow	May 25th to 31st	42	1
Greece, Athens	May 18th to 25th	2	
India, Calcutta	May 4th to 11th	..	34
Karachi	April 28th to May 12th	9	3
Italy, Naples	May 19th to 26th	161	28
Japan, Nagasaki	May 6th	1*	
Tokyo	May 11th	3	
Manitoba, Winnipeg	May 25th to June 1st	2	
Mexico, Mexico City	May 19th to June 2d	..	3
Russia, Odessa	May 11th to 26th	9	1
St. Petersburg	May 4th to 18th	24	5
Warsaw	May 4th to 11th	..	8

* On United States steamship *Indiana*.

Yellow Fever.			
Mexico, Vera Cruz	May 18th to 25th	..	1
Cholera.			
India, Bombay	May 7th to 14th	..	3
Calcutta	May 4th to 11th	..	47

Plague—Foreign and Insular.			
Africa, Cape Town	To April 5th	412	181
China, Hong-Kong	April 20th to 27th	65	55
India, Bombay	May 7th to 14th	..	289
Calcutta	May 4th to 11th	..	134
Karachi	April 28th to May 12th	657	563
Japan, Formosa	May 3d to June 1st	2,157*	
Philippines, Manila	April 13th to 20th	27	16

* Increasing from May 19th.

COFFEE AS A BEVERAGE, AND ITS FREQUENT DELETERIOUS EFFECTS UPON THE NERVOUS SYSTEM: ACUTE AND CHRONIC COFFEE POISONING.[1]

BY WILLIAM M. LESZYNSKY, M.D.,

NEW YORK,

CONSULTING NEUROLOGIST TO THE MANHATTAN EYE AND EAR HOSPITAL; NEUROLOGIST TO THE DEMILT DISPENSARY, FELLOW OF THE NEW YORK ACADEMY OF MEDICINE, THE AMERICAN NEUROLOGICAL ASSOCIATION, ETC.

COFFEE when well prepared is beyond question one of the ambrosial luxuries of modern life. Owing to its abundant production, its comparative cheapness, and its simplicity of preparation, its use has become conventional among all conditions of mankind. To condemn it indiscriminately as injurious might shake the faith of multitudes, and would be equivalent to an admission of ignorance as to its universally recognized value, and an exposure to the suspicion of abetting the propaganda of anti-coffee agitators. The purpose of this paper is briefly to demonstrate that ill-effects following the use of coffee are by no means uncommon.

Since I began to investigate this subject, about ten years ago, I have had ample opportunity, from clinical observation, to form a correct estimate of its importance. The more I have studied the question, the more firmly have I become impressed with the fact that such an apparently trivial matter has undeservedly escaped the consideration, at least in this country, that its importance demands. The discomfort or danger often arising from the injudicious or excessive use of coffee, and its increasing consumption within recent years, warrants me in calling your attention to the prevailing abuse of this valuable commodity.

"In roasted coffee are found caffeine and caffeone, and the activity of the product depends upon their presence. The latter consists of the volatile substances developed in the process of roasting. Among these is caffeol, an empyreumatic oil. Caramel is also formed by the conversion of the sugar contained in the seed. While the caffeine exerts the larger part of the physiological action of coffee, much of it depends on the volatile substances. The cerebral stimulation and activity produced by a cup of coffee are thought to be largely due to caffeone, since they are but slight after the administration of an infusion of raw coffee, although caffeine is present in it in the same degree. Moreover, experiment has shown that caffeone is opposed to caffeine in its action in at least one direction, for the effect of the isolated caffeone is to accelerate the heart's action and lower the blood pressure, whereas the effect of caffeine is the opposite."[2]

Isolated caffeone is not administered outside of physiological laboratories, while caffeine, as a rule, is prescribed as a cardiac and respiratory stimulant, and also as a diuretic. Everybody is familiar with their combination as coffee, hence I shall confine my remarks to coffee as a beverage, in the form of decoction or infusion, and its effects upon the nervous system.

Many show no discretion in its use, and while we all appreciate its beneficial influence in the economy, we are forced to the conclusion that its thoughtless abuse inevitably results in unpleasant consequences. It would require a special paper to extol the great medicinal value of coffee, for we all realize its excellence as a therapeutic agent. Its universal use as a beverage, however, greatly restricts its usefulness as a medicine. To the majority, its taste and action are agreeable. For others it is really a poison.

According to the report of the United States Department of Agriculture, in 1892. the quantity of coffee imported into the United States was 632,941,912 pounds, at a valuation of $126,801,607. From 1892 to 1896, the average annual importation was 597,484,217 pounds.

In 1897,	737,645,670	pounds, at a	valuation of	$81,544,384.
In 1898,	870,514,455	"	"	65,067,631.
In 1899,	831,827,063	"	"	55,275,470.

From these figures, it will be observed that, in the year 1898 alone, the importation reached the prodigious amount of 870,514,455 pounds. It will also be noticed that the price of coffee has undergone a material and progressive decrease since 1892. We can thus readly appreciate that the demand for, and consumption of this article have been rapidly extending disproportionate to the needs of our ever-increasing population. The people of the United States consume, it is said, about one-third of the total coffee production. From this assumption (and there is no valid reason to doubt its correctness), we may account, in a great measure, for the prevailing nervous characteristics of many of our population, their increasing mental activity, and the actual accomplishment of work that might otherwise be impossible.

As coffee is an antidote to alcohol, so far as the nervous system is concerned, it is not uncommon for both to be used excessively by the same individual. While coffee often induces disordered nerve function, which is always remediable when the cause is recognized, the persistent use of alcohol, on the other hand, may ultimately lead to incurable structural changes. Love, in an interesting paper on "The Use and Abuse of Coffee,"[1] concludes that "in excess it is even more dangerous than alcohol, for it is not, like the latter, a nutrient, nor is the effect of its excessive use so apparent or unrespectable." Recognizing the immediate possible consequences of habitual alcoholic indulgence, and its demoralizing influence, it is but natural that so many of us prefer to resort to the use of coffee to tide us over certain intellectual emergencies.

The intellectual faculties excited to the greatest degree by the use of coffee are the imagination and the memory. It produces an augmentation in the power of attention, a vivacity of thought and conception, increased capacity for mental and physical work, and

[1] Read before the New York County Medical Association, December 17, 1900.

[2] "Pract. Therap.," Foster, vol. i., p. 289.

[1] Journ. Am. Med. Ass'n, February 14, 1891.

transitory ambitions often beyond the physical or mental capability of the individual. The potentiality of coffee, as above described, has thus proved both a blessing and a source of danger to modern civilization.

The matutinal cup of coffee has become almost indispensable to many, simply through time-honored custom and tradition, and it unquestionably has a beneficial and wholesome effect on the vast majority of our adult population. Were it not well known, however, that the habitual use of coffee is often intolerated, and frequently proves injurious to a large class of people, so many alleged substitutes would not be on the market. Reichert[1] has shown that the virtues of coffee in the vicissitudes of active life are entirely subjective, and depend upon its exhilarant action on the mental processes. The popular idea that coffee can replace food, or increase the power for work without corresponding tissue waste, is entirely erroneous.

In the search for the cause of obscure nervous phenomena, it is always necessary to inquire closely into the daily habits of the patient, as well as to investigate his or her antecedent history. This is particularly true in regard to the consumption of food, the indulgence in alcoholic liquors, and the use of various beverages. Although of rather common occurrence, it is often astonishing, nay, even marvellous, to witness the disappearance of inexplicable symptoms soon after the discontinuance of certain customary articles of diet. While idiosyncrasy may be considered a factor of paramount importance in many persons, in others the peculiar susceptibility to the influence of certain food products is often augmented through their excessive and continual use. To those who have given no thought to the matter, it may seem incredible that such an article as coffee, which is a part of the daily dietary in almost every household in the land, should also find its victims. The ancient adage, "What is one man's meat is another man's poison," is often well exemplified in regard to coffee. One man will sleep well all night, after drinking a cup of strong coffee before retiring, while another will suffer from insomnia after a much smaller quantity. It seems to be a rather popular belief among the people that coffee possesses no injurious qualities, and may be taken *ad libitum;* others have not considered the matter at all, and most physicians have given the subject very little if any attention. In my opinion, it is just as necessary (and much easier) to inquire as to the patients' habits in regard to coffee, tea, and cocoa, as it is to question them as to their use of alcoholic stimulants. Thousands of oversensitive persons complain that a single cup of coffee at once induces in them a transitory sensation of well-being, increased rapidity of thought, etc., which is soon followed by a feeling of apprehension, general tremulousness, and indigestion. If a smaller dose were taken, commensurate with their susceptibility, the secondary objectionable symptoms would often fail to appear.

The habitual daily indulgence in coffee, even in moderate quantity, by those who are oversensitive to its action, invariably leads to persistent functional disorder of the nervous system, as well as to disturbance of digestion, which rapidly subsides when it is discontinued. No doubt the latter is often occasioned by the addition of too much milk and sugar, which favors the process of fermentation. Whether or not the general nervous symptoms are to be considered secondary to the disturbance of digestion, further investigation will determine. Some physicians believe that coffee without the customary milk and sugar never disturbs the gastric function. While this assertion is often substantiated by clinical observation, it must not be accepted without reserve, for digestive trouble frequently occurs also in those who indulge excessively in coffee, without the addition of either milk or sugar. In some instances, it is possibly aggravated by coffee of an inferior quality or by various adulterants. Leven[1] believes that the action of sugar and that of coffee are antagonistic. He says: "Coffee produces anæmia of the gastric mucous membrane and diminishes its secretion; if this be often repeated it terminates in a hyperæmia, a congestion which in itself is the cause of the dyspepsia. Sugar, on the contrary, excites the gastric secretion, hence it is necessary to sweeten the coffee." This theory, however, has found no support.

Many or all neurotic individuals seem to be more or less susceptible to the influence of coffee, particularly in regard to its effects on the nervous system, and it usually aggravates any existing hyperæmia in the cerebral circulation. I have seen quite a number of persons in whom coffee produces paroxysmal sneezing and coryza, and others in whom pruritus, either local or general, becomes a pronounced and troublesome symptom. I can recall several cases of pneumonia and typhoid fever, in which caffeine had been taken every two or three hours as a cardiac stimulant. During its administration the patients suffered from insomnia and restlessness. As soon as its use was discontinued, these symptoms promptly disappeared.

Among others, Dr. Norman Bridge,[2] of Chicago, has observed that coffee-drinking is a frequent cause of disease, and he reports in detail the histories of seven cases in which many obscure symptoms were present. All recovered when they dispensed with the use of coffee. Although I have abundant records at my disposal which will more fully illustrate the views herein expressed, nothing will be gained by a lengthy report of corroborative cases. In several patients, I have been able to trace to the daily use of coffee the otherwise unexplained cause of vertigo, either through its direct action on the vascular system, or indirectly through disturbance of gastric digestion.

The wakefulness and flow of thought produced by coffee are rather commonplace knowledge. Thus, many trained nurses are unable to do night duty without partaking of several cups of coffee during the night, and I have noticed that a large number of them use either coffee or tea excessively; also many nervous literary men and women, and business men under high pressure, continually resort to the coffee-cup for cerebral stimulation and a renewal of their flagging energy. The abuse of coffee in this manner insidiously if not rapidly leads to various degrees of exhaustion of the cerebro-spinal centres. This fact cannot be stated too emphatically, especially regarding those who react readily to this form of stimulation.

The nervous system of children is peculiarly susceptible to the effects of coffee, and its use should never be permitted. It produces a certain intellectual precocity through overstimulation of the cerebral cortex, as well as other functional disturbances. While it is customary to hear the parents of nervous children among the poor say with pride that their children "eat and drink everything," it is not unusual among the well-to-do to have them admit that they give their children both coffee and tea. I have often seen "night terrors," insomnia, and tremulousness disappear after the withdrawal of coffee from the dietary. Guelliot[3] has observed several cases of arrested physical development, particularly of the sexual organs in male children, as a result of the excessive use of coffee. Several years ago, I attended a healthy boy six years of age, who suffered from acute coffee poisoning. When I saw him at 10 P.M., in one of the hotels in

[3] Union méd. du nord-est, 1885.

Saratoga, he was in a condition of active delirium, with widely dilated pupils, tremor in the facial muscles and extremities, and severe tachycardia, the pulse rate being 200 beats a minute. Visual and aural hallucinations were present at intervals for five or six hours. He had entered the barroom of the hotel late that afternoon, and taking a handful of roasted coffee beans from the counter, had eaten about a half-ounce during the evening. He recovered completely at the end of a week. Rugh[1] has reported a case of coffee poisoning in a travelling salesman thirty years of age, who, for three weeks, drank from ten to twelve cupfuls of strong, black coffee daily. This resulted in a condition resembling delirium tremens. He recovered after suitable treatment. Cases of acute coffee poisoning have also been reported by Curschman,[2] Müller,[3] and others.

There is a distinct type of cases of rather frequent occurrence, particularly among the poorer class of people, but by no means strictly limited to them, which manifests itself in a form of functional nervous disorder, to which the elastic term "neurasthenia" in its broadest significance may be aptly applied, and which is due to the excessive use of coffee. After carefully investigating and treating several hundred of these patients, I feel justified in calling your attention to a common group of symptoms, most frequently observed in those addicted to the excessive use of coffee, constituting a condition that should best be designated as the "coffee habit," or "chronic coffeeism."

As a large proportion of the patients who consult the neurologist complain of "nervousness," it is evident that abundant opportunity is thus afforded for the study of such cases. I have seen victims of the coffee-habit among commercial travellers, brokers, merchants, actors, writers, and men connected with the news departments of the daily papers. In fact, they are strikingly frequent among those who are working under high pressure, and whose occupation requires a great deal of talking or mental activity. In order to produce the desired stimulation, they find it necessary continually to increase the dosage, just like those who have the "alcohol habit" or the "opium habit." Their general health becomes much impaired, and the functional activity of every organ may be affected. They usually complain of the following symptoms, which are more or less pronounced, and in varying combination: general headache and "nervousness"; apprehension in regard to some unknown impending trouble; mental depression and irritability; insomnia or restless sleep; "bad dreams"; sudden "starting" in sleep and awaking in profuse perspiration; occasional or frequent vertigo; general tremulousness and diminished muscular power; precordial oppression; cardiac palpitation; loss of appetite; frequent eructation of gas, and constipation. The symptom complex most commonly noted is: general nervousness; tremor; vertigo; restless sleep; cardiac palpitation; eructation of gas, and constipation. On examination we usually find a coated and tremulous tongue; tremor in the eyelids while standing with closed eyes; in some, the pupils are slightly dilated, but react quickly to light; tremor in both outstretched hands; rapid pulse, of low tension and frequently irregular, ranging from 90 to 130; exaggerated reflexes, and more or less increased reflex irritability. Tachycardia or bradycardia may also be present.

It must be admitted that this entire series of neurasthenic symptoms may result from other causes, such as the excessive use of alcohol, tea or cocoa, or from a combination of several factors. As a general rule, it is most frequently mistaken for chronic alcoholic toxæmia. It is not difficult to determine by a process of exclusion, however, that the condition in question is beyond any doubt attributable to excessive coffee drinking. Very often some of these patients are intemperate in other directions, or they may also be addicted to the use of alcohol. In my experience, the majority of those who suffer from the results of the "coffee habit," drink alcoholic or malt liquors either only occasionally or not at all, being satisfied with the cerebral stimulation produced by the coffee. It is not unusual for many of them to drink from six to eight cupfuls of coffee daily, while some have been known to drink from twelve to fourteen cupfuls in as many hours. In some, symptoms of chronic poisoning may result from three or four cupfuls daily. Such persons do not take suitable or sufficient food, and as coffee possesses but little nutritive value, they ultimately show unmistakable evidence of malnutrition in addition to their other symptoms.

In this connection, it is interesting to mention that physiological experiment has shown[1] that after substituting infusion of coffee for water, inanition became more marked in those animals fed only upon hydrocarbons, while in those fed exclusively upon meat, the malnutrition was not so pronounced. This fact may explain the loss of weight among the poor patients of this class, whose dietary consists principally of carbonaceous food.

There is a peculiar difference between the symptoms of acute and chronic coffee poisoning. In the former, when coffee is taken in large doses by persons unaccustomed to its use, it produces excitability to the degree of delirium, etc. In the latter, which is of greater importance on account of its more frequent occurrence, the toxæmia manifests itself as a depressive form of neurasthenia. In brief, the symptoms of chronic coffeeism are indicative of interference with the nutrition of the cells of the cerebro-spinal system resulting from overstimulation and auto-toxæmia, and correspond very closely with the symptoms of chronic alcoholism, for which it is so often mistaken.

Age, sex, temperament, constitution, and occupation, which occasion individual susceptibility, must be considered prominent predisposing factors in this disease. For obvious reasons, women are more addicted to the coffee habit than men.

Although the effects of the abuse of coffee have been known since 1705,[2] and have been mentioned from time to time during the nineteenth century by several French and German observers, the importance of the subject has never been adequately realized in this country. Errors in diagnosis frequently result from the failure to recognize such a potent element as the abuse of coffee as a factor in the causation of neurasthenia and seemingly obscure nervous phenomena. It can be safely said that those who will look into the matter will no doubt discover a surprisingly large number of such patients.

In a classical article, entitled "Du caféisme chronique," which is deserving of careful study, Guelliot[3] reports at length the histories of seventeen patients, twelve females and five males, who had been in the habit of drinking from three to sixteen cupfuls of coffee daily. The digestive function was the first attacked. At times there was epigastric pain radiating to the dorsal region. It was of the same character as the other neuralgias to which these patients are subject. At other times there was vertigo among other symptoms. The pulse was slow, soft, and compress-

[3] Union médicale du nord-est, 1885.

ible. The tremor disappeared for a time after a dose of coffee just as in chronic alcoholism. He also speaks of sexual impotence in the male, and profuse leucorrhœa in women as prominent symptoms.

Mendel[1] has likewise called attention to the functional disturbance of the nervous system produced by the excessive use of coffee, and he has reached the positive conviction that coffee, when used excessively for a long time, produces a characteristic clinical picture with a definite symptom complex similar to that herein mentioned, but of the most pronounced character in his cases. He concludes that the chronic misuse of coffee produces its injurious effects in the same manner as alcoholism and morphinism, and he graphically describes a class of workingwomen in one of the industrial districts in Germany, where they consume large quantities of coffee daily. "At every meal, from early morning until late at night, the workingwoman drinks her coffee, which always stands ready on the stove. The coffee energizes them to work, stills their hunger, cheers them in misfortune; in short, what the whiskey flask is to the laborer, the coffee-pot is to these women."

The same condition has also been observed in France under like circumstances. Gilles de la Tourette and Gasne[2] have reported two cases, and also call attention to the possibility of mistaking it for alcoholism. Viaud[3] has observed that "all the large consumers of coffee have a slow pulse, from 40 to 60 beats a minute; a few have gastric oppression, and others have some pyrosis, but they complain only of the head and not of the stomach. Vertigo, tinnitus, blurring of vision, and sensation of falling are the principal symptoms." He has come to the conclusion that in all the cases of stomachal vertigo (the so-called vertigo a stomacho læso of Trousseau) there has been abuse of coffee, and asserts that he has never observed this form of vertigo in those who abstained from its use. In only a few instances that have come under my observation has bradycardia been present. While vertigo has been very commonly complained of, it has rarely been pronounced. Combemale,[4] in reporting a case and discussing the subject of "caféisme chronique," expresses the view that while the caffeone contained in coffee may add to the excitation, like the essences in certain alcoholic preparations, it is the caffeine which produces the "caféisme chronique," just as chronic alcoholism is the result of alcohol.

The essences, such as caffeone and absinthe, etc., give only a special color to the intoxication. This theory, however, has not been definitely substantiated. At any rate, it is at present practically immaterial whether the toxæmia is due to the caffeine or the caffeone contained in the deservedly popular beverage known as coffee.

In the treatment of these patients, I do not recommend in every case immediate and total abstinence. As a general rule, their allowance should at once be limited to one cup of coffee in the morning. If necessary, its strength should be gradually reduced or its use absolutely prohibited. The customary stimulant being suddenly withdrawn, if careful instructions are not given, the patient will soon find a substitute in tea or cocoa, or possibly alcohol. An infusion of cacao-nibs in moderate quantity frequently proves acceptable in place of coffee. There are many preparations on the market under various names, and generally advertised as "substitutes for coffee." They are known to contain parched corn, peas, beans, and corncobs, as well as sweet potatoes cut into small pieces, dried and parched. Chicory is commonly used mixed with true coffee. The manufacturers of more recently vaunted substitutes claim that their special preparations are made of cereals. I have long since refrained from recommending any of them, as their continued use soon leads to disturbance of digestion. While cocoa possesses considerable nutritive value, its principal alkaloid is theobromine, which is almost identical with caffeine in its chemical and physiological effects. With but slight qualifications, the same may be said of tea and its alkaloid theine. Hence the use of cocoa and tea must also be restricted or forbidden. Suitable hydriatric treatment, and careful attention to the diet and excretions, should be systematically carried out. In some cases it may be necessary to institute a "rest cure."

As a sedative to the nervous system, and also temporarily to replace the accustomed stimulation, it has been my routine practice to prescribe the following mixture to be taken in water three times a day. Sodium bromide, gr. xv.; liq. potass. arsenit., ♏ ii.; tinct. gentian. comp., ʒ ss.; ext. kola fld., ♏ xv. At the end of five or six weeks the bromide, etc., should be discontinued, and tonic pills containing arsenic, quinine, and strychnine, or some similar combination taken daily for several months. Under the foregoing plan of treatment, faithfully followed, most of these patients will completely recover within three to six months.

AN IMPROVED METHOD OF PERFORMING SUPRAPUBIC CYSTOTOMY.[1]

By C. L. GIBSON, M.D.,
New York,
Attending Surgeon, St. Luke's Hospital; Visiting Genito-Urinary Surgeon to the City Hospital.

The suggested improvement in the technique of suprapubic cystotomy refers to the detail of drainage. It consists in utilizing for the urinary bladder the principle that has proved so successful in the creation of a permanent gastric fistula—usually known as Kader's operation—which in simplicity of application and effective results must be considered the standard operation of the present day.

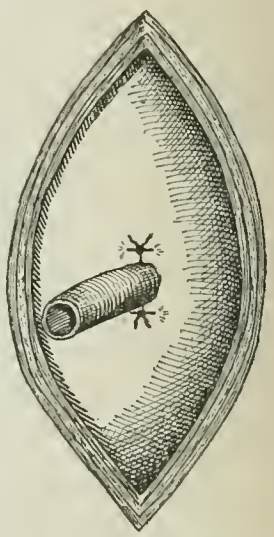

Fig. 1.—Tube Placed in Vesical Opening. A stitch on either side diminishes the size of the cut.

A tube is placed in the stomach opening, and the incision, if necessary, is reduced to a size that permits of a snug fit. A fold of stomach wall is now brought around the tube by passing one or more of Lembert sutures on either side of the tube. These sutures having been tied, a second set is applied in like manner, increasing the depth of the burial of the tube in the stomach wall. A catgut stitch is passed through the stomach wall and the tube, effectually securing the latter in place. The stomach is finally anchored to the peritoneum and abdominal wall.

After some days a permanent sinus is formed. It hugs the tube closely, preventing escape of gastric contents while it is *in situ;* when the tube is removed,

[1] Read before the Section on Genito-Urinary Diseases of the New York Academy of Medicine, October 17, 1900.

it takes on the function of a valve, from the inversion of the cone-shaped area of the stomach wall.

This principle has also been most satisfactorily applied to drainage of the gall bladder. The writer also hopes eventually to report a similar field of usefulness for it in certain procedures on the intestine.

In determining to apply this operation to the urinary bladder, the writer hoped to attain a threefold purpose.

I. Effective drainage of the bladder without leakage.

II. Rapid closure of the fistula on discontinuance of the drainage.

III. The creation of a permanent sinus which should allow of permanent but periodical catheterization of

With regard to the third and most important point the writer hesitates as yet to formulate an opinion, as he has only twice performed the operation and the after-care of these cases passed from his control, so that the test has not been a fair one. He believes that the desired result can be obtained, though probably not without some rather greater elaboration of the present operative technique. Could the fistulous walls be lined with serous membrane there should not be the slightest difficulty in accomplishing the desired result. In one of his operations the writer made a tentative effort to drag the peritoneal reflection farther downward over the bladder, in which case the fistula

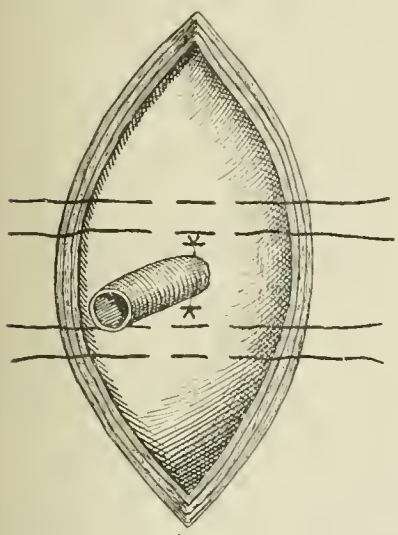

FIG. 2.—The First Row of Inversion Sutures in Place, Ready to be Tied.

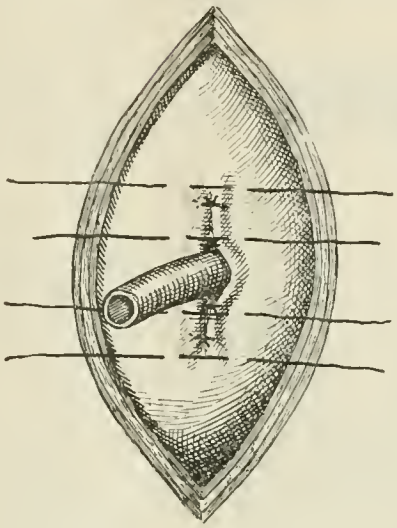

FIG. 3.—The First Row of Inversion Sutures has been Tied; second row in place, ready to be tied.

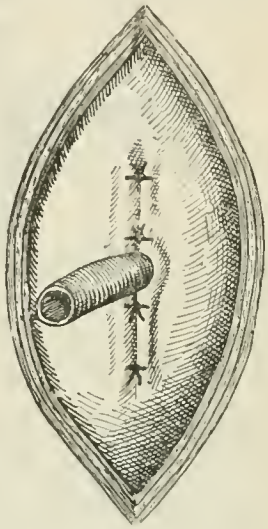

FIG. 4.—Second Row Tied. Operation completed.

the bladder, and in the intervals, owing to its valve action, prevent escape of urine, and do away with the discomfort of wearing a tube or dressing.

There could have been no question about obtaining these results, viewed from the success of the procedure on the other hollow organs mentioned, provided we had the same conditions to work on. The weak point in this operation, when applied to the urinary bladder, is found in the absence of peritoneum, which, owing to its adhesive qualities, is the main element of success in the gastrostomy.

So far as one can speak from a limited number of cases, the first two expectations have been amply justified by practical experience. The drainage secured is absolutely perfect, the wound healing consequently most satisfactory.

Dr. P. R. Bolton, attending surgeon to the New York Hospital, honored me by making trial of this device with most gratifying results. Suprapubic cystotomy for stone in an adult male, and suture of bladder by inversion around the drainage tube, were performed, with absolutely no leakage. On the third day the tube accidentally came out, and remained out some hours; during this time there was no leakage. The tube was removed on the fourth day, and from that time on, not a drop of urine escaped from the opening. The patient was up on the fifth day, and discharged on the seventh. In this case the closure of the bladder might well be called instantaneous.

Since this communication was read, several gentlemen have kindly tried this method, and from their reports to the writer the expectations entertained in regard to perfect drainage without leakage and speedy closure after withdrawal of the tube seem to have been justified. Dr. L. Bolton Bangs reports that he drained a bladder for fourteen days without leakage. On taking out the tube the closure was so prompt that there was only enough escape of urine to moisten slightly the dressing for a day or two.

would have been established through this fold, but the attempt was unsuccessful.

Another possibility that suggested itself was the turning down of a peritoneal flap from the middle line over the bladder. If the resultant defect could be satisfactorily repaired this step might be quite satisfactory.

Undoubtedly the most desirable operation technically would be to reproduce the actual conditions of the gastrostomy, that is, to perform abdominal section, bring the bladder into the wound, and establish the fistula through tissues that insure success. Such a course adds a serious element of danger, and one has to determine the probable value of the results to be obtained as contrasted with the danger incurred.

If other less serious measures fail to accomplish the desired result, the writer feels that he shall eventually resort to this last method. He believes so strongly in the efficacy of the fistula thus established that he considers that if once established it is practically devoid of risk. The chief danger would consist in the possible infection of the abdomen during the manipulations incident to the operation. While realizing his responsibilities in this direction, the writer would be quite ready from his experience in abdominal surgery to accept them with considerable confidence as to the outcome. This opinion is influenced greatly by the writer's belief in the advantages of the operation, which he is inclined to take seriously.

The patient with a successful gastrostomy wears neither dressing nor tube. At appropriate intervals a catheter is passed by himself with perfect ease, and the stomach receives a considerable amount of fluid. On withdrawal of the tube there is no leakage, and none can be produced by any kind of exertion or posture. There can be no doubt, so the writer believes, that this condition, could it be reproduced in the urinary bladder, would be the ideal means of healing permanent obstruction to the urinary outflow which could

not be remedied by simple methods. If this ideal method could be established certainly much comfort could be given to patients who, by virtue of their condition or the danger of radical operations necessary for their relief, are condemned to drag out a most miserable existence.

As performed by the writer this operation consisted in snugly surrounding a tube of suitable calibre (32 F.) by an inverted cone of bladder wall (care being taken to secure a good denudation of the bladder), exactly as has been described for the stomach. The accompanying diagrams show the exact steps. The ends of the second row of sutures are left long, and are carried through the abdominal wall, which is closed

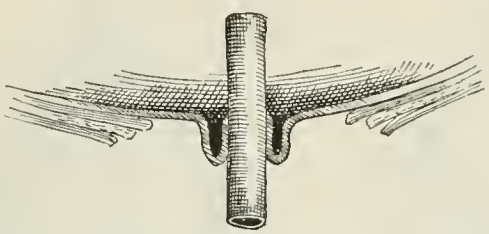

Fig. 5.—Result of Inversion as Seen from the Interior of the Bladder. When the tube is withdrawn, the falling together of the inverted vesical folds acts as an efficient valve.

snugly by sutures through the musculo-aponeurotic layer, only sufficient space being left for the exit of the tube.

The writer has had a special double tube made by Stohlmann, Pfarre & Co., which allows of convenient irrigation of the bladder without any disturbance or interruption of the drainage.

The drainage is effected by leading the tube into a receptacle which does not need to be filled with any fluid. No siphon arrangement, or in fact any other extraneous aid is required to obtain perfect drainage without the slightest leakage alongside of the tube.

In conclusion the writer would beg to say that he offers this procedure as a thoroughly efficient and simple method of drainage, also as the speediest method of securing closure of a fistula. Besides, he hopes by further efforts to give it a recognized position among the measures destined to relieve chronic urinary obstruction.

SOME REMARKS ON THE MODERN SURGICAL AND MEDICAL TREATMENT OF EPILEPSY.[1]

By L. PIERCE CLARK, M.D.,

FIRST ASSISTANT PHYSICIAN, CRAIG COLONY FOR EPILEPTICS, SONYEA, N. Y.

Epilepsy is generally held to be a disease of the cerebral cortex. Notwithstanding convulsions may be educed from the basal ganglia and even from the spinal cord itself, such phenomena lack many of the essentials of true epilepsy. Epilepsy is a complex sensorimotor phenomenon, an intricate reflex symptom complex.

The exact balance is not yet struck as regards the relative importance of the immediate excitant in epilepsy and that of the hereditary or acquired predisposition of the disease. However great the immediate provocation of a convulsion may appear in some cases, in the vast majority the far greater rôle is played by the predisposition. Before the problem of how much is due to predisposition is solved, an immense amount of detailed study must be done upon general or cell physiology and cell chemistry, to say nothing of the vast unknown domain that lies beyond in the genesis of psycho-motor phenomena. A great number of able investigators have been working in this fruitful field of general or cell physiology, whose sole pioneer long ago was the master physiologist, Johannus Muller. It is, therefore, evident that to-day's investigations upon the nature of the mental and nervous diseases need to be along all correlated lines of scientific investigation.

The studies by the newer methods upon the epileptic cortex seem to be paving the way, slowly but surely, to the establishment of idiopathic epilepsy in the category of the organic brain lesions. with a demonstrable substratum. During the past four years Dr. Prout and myself have been engaged in the study of status epilepticus. We have carefully examined some forty-five epileptics in about one hundred and fifty different status periods; thirteen selected cases have come to autopsy and have been under careful histopathological study.[1] In these thirteen cases uniform histological changes were found as follows: A degeneration of the nucleus of the second or so-called sensory layer; further, a willingness for the nucleus to suffer extrusion from the nerve cell; a chromatolysis of the whole cortex, especially in the motor region; phagocytosis of the constitutent nervous elements by infiltrating leucocytes, and last of all, in the most progressive cases, a nodular or disseminated sclerosis, new formed under what is usually termed degenerative repair, a proliferation of the neuroglia. The cortical sclerosis was unevenly distributed and was probably the last and permanent set scene of this disease, played in the gray mantle of the epileptic brain.

When we take into account that to jeopardize the cell nucleus is to endanger the life of the cell, that the nucleus presides over cell metabolism and energy, we see how very vital degenerative lesions of this cell element may be to the integrity of the cerebral cortex.

If these lesions should be found to be constant, to what extent would they solve the epilepsy problem? They would prove only that epilepsy is accompanied and followed by a definite organic lesion of a marked and widely degenerative nature. The lesions are probably both a cause and an effect of the disease. We would know that the nervous storm had occurred and left a track of destruction, but our knowledge of the exciter of the storm and the degree of resistance it had met from the tissues would be but little or not at all enriched. While the dawn of light in the domain of the etiopathology of epilepsy enchants but a few votaries, the daily problems of empirical treatment of epilepsy are of interest to all, and demand our close attention and study.

Surgical Treatment.—At the outset of the consideration of the surgical treatment of epilepsy, I wish to re-emphasize the importance of careful medical treatment before and after trephining. Cases treated surgically need to be under the physician's care, except for the time they may be in the operating-room.

The rules which govern the selection of cases for trephining need to be more restrictive than at present conservative medicine demands. If this were done, a much better prognosis for recovery would obtain for the traumatic cases than the present four per cent. From the class of those heretofore supposed to be operable, I would urge that iodiopathic epileptics in whom the seizures have a definite form of invasion be withdrawn. True or essential epilepsy frequently takes the Jacksonian form in point of muscular involvement in seizures. Many traumatics probably owe the focalization of their convulsions as little to trauma as the true idiopathics with Jacksonian convulsions. The brain, as a whole, in such cases is epileptogenic, one zone is only a little more excitable

[1] Read before the Buffalo Academy of Medicine, November 13, 1900.

[1] Abstracts of the clinical and pathological work were presented at the New York Neurological Society October 2d and will soon be published in full.

than another. Much disappointment has been experienced by surgeons operating upon these idiopathics disguised as Jacksonian epilepsy.

In Jacksonian epilepsy with well-marked cranial trauma, when but little or no neurotic family history is present, we may trephine with advantage within two years after the injury and the onset of the epilepsy. In such cases we can expect excellent chances of recovery, providing post-operative treatment is persistently followed. According to the prominence of the convulsive tendency or habit, the time between the establishment of the epilepsy and the performance of a successful operation must be lessened.

I feel that in the vast majority of cases in which cranial injury is not boldly in evidence, the trauma could not have been a material exciter to the epilepsy. Almost all epileptics receive frightful falls, contusions, and lacerations of the scalp in almost daily attacks of their disease, covering a number of years, and yet the finding of intracranial injury, hemorrhage, and contusions of brain substance at autopsy as a result of the epileptic accidents are exceedingly rare.

It is a surprising fact that traumatic epileptics have such neurotic family histories; often they are quite the equal of the idiopathic variety. This fact should not be lost sight of, as it often materially changes the prognosis of ultimate recovery. A neurotic history in Jacksonian epilepsy tends to prove to us that in all epilepsies, from whatever initiative, the predisposition is paramount. An illustration of the neglect to take into account the bad family history in traumatic cases may be cited briefly in one case which came under my notice recently. The patient was trephined for an indefinite history of cranial injury; the surgeon found nothing especially wrong on trephining; the definite order of muscular invasion which largely induced the operation continued after trephining as before, just as it always does after operation on idiopathic epilepsy. To make the prognosis still worse, the patient was allowed to go without special post-operative treatment. The surgeon advised operation without a single inquiry into the family history, which was as follows: The mother died of apoplexy and epileptic convulsions; a paternal uncle died epileptic and insane; one of the patient's sisters died in infantile convulsions; a brother had a laryngeal tic, and the patient himself had infantile convulsions, independent of dentition. This single illustration is but one of many that have come under my own observation.

Many cures by trephining are reported successful too soon after operating; not a few surgeons still report cures by trephining after but a few weeks' or months' freedom from seizures. A few months ago the illustrious Van Gehuchten reported a cure from trephining after the patient had had an immunity from seizures for but five months. He called the cure permanent. The physician has long since learned his lesson in this regard, and now waits at least several years before reporting a cure, and in many instances he joins the extremists and calls all cessations from attacks, remissions, and warns the patient of a possible return of the disease in thirty or forty years.

In advising operation by trephining, we should remember that a fairly large percentage of those trephined are not only not benefited, but are actually made worse by operation. Many of such have been reported recently both in this country and abroad. This seems to be due in part to the formation of cicatrices, adhesions between membrane and cortex, or other irritation of the cerebral cortex. Unfortunately, no known method is yet entirely successful in preventing a re-formation of old adhesions. Kocher frequently reoperates for this condition and post-operative intracranial pressure.

Operating in epilepsy for the relief of intracranial pressure as a primary cause of the convulsions is no longer practised. The extra pressure is a result of the convulsion and not a cause. Notwithstanding this, Kocher, who has done twelve operations in carefully selected cases of late, has secured six radical cures. In addition to other precautions, he arranges for an after cerebral and cranial drainage. It is logical to expect an increase of intracranial pressure after operation, and recent observations and statistics prove the theory. Kocher's results were, nevertheless, best in the cases showing adhesions between the dura and pia, and with him the more radical the interference the better were the results. Probably we can attribute much of his success to the fact that he did not neglect a post-operative bromide treatment, and that he selected cases largely with an absent neurotic history.

Many idiopathic epileptics in whom Jacksonian seizures predominate are proving themselves to-day to be due to infantile cerebral palsies which were previously overlooked. When great atrophy and deformity of the limbs from these cerebral lesions are in evidence, they are detected by the novice, but the most expert frequently fail to detect the slighter symptoms of cerebral palsies in children. The frequent inability to detect these early cerebral lesions led Freud to hazard the statement that a majority of idiopathic epileptics with Jacksonian phenomena have had infantile cerebral palsy once, but years later no symptom of the palsy exists except the epilepsy. I may say, in passing, that careful attention to the reflexes on different days and different times during the same day, and close study of the associated and dissociated movements, will give us valuable aid in diagnosing an early palsy in adult epileptics.

A paresis or a weakening in parts first and most convulsed—a symptom upon which many surgeons advise operation—should lead us to try to exclude infantile cerebral palsy first. It was in just such cases that exhaustion paralysis or paresis was first observed nearly a century ago. It is needless for me to say that trephining in the infantile cerebral palsy epileptics can do no good.

In regard to the operation of trèphining itself, it is generally conceded that large patent openings should be made in trephining, no attempt being made to secure any bony occlusion; this should be done both for the thoroughness of operation and largely to prevent a possible increase of intracranial pressure and meningeal adhesions. The large openings are also advantageous in focalizing the area wanted, as we must make allowance for individual variation in motor areas. The individual variation in one of my cases, recently under operation, required two large trephinings to strike the area wanted, although Ferrier's charts were used.

As to tumors producing Jacksonian epilepsy, present-day statistics show that but two per cent. of them are ever operable even for the relief of other possibly more dangerous symptoms.

To summarize the present status of trephining:

1. Idiopathic epileptics with typical grand-mal seizures should never be trephined.

2. Idiopathics in whom seizures are of the Jacksonian type should be trephined only when infantile cerebral palsies can be excluded, and when the family and personal degeneracy is at a minimum; if operation is determined upon in such cases, a very thorough removal of the epileptogenic area should be made; even then but a fraction of one per cent. recover from their epilepsy.

3. Traumatic epileptics may be trephined when the injury is definitely proven and stands in direct causal relation and has existed not more than two years. The prognosis will then largely rest upon the degree of the neurotic predisposition present. The earlier

trephin...g is resorted to after convulsions begin, the better the prognosis.

If these rules are followed, many less so-called traumatic cases will be trephined, but the result will far exceed four per cent. of recoveries. All epileptics trephined for whatever cause must be given post-operative bromide treatment for years.

Medical Treatment.—It probably will not be necessary for me to say that the perfunctory administration of any specific for the cure of epilepsy is no longer considered good practice. The entire living regimen of each patient must be specified, including vegetative, hygienic, and psychic life. All disordered functional processes of the body must be corrected, and internal and external cleanliness must be maintained. The work, education, and play of the epileptic are legitimate tools for regulating his disease. In short, the whole life of the epileptic must be re-established; the broader, the more comprehensive, and the more detailed the regulations shall be, the greater will be the success with the individual case. Many epileptics are life-long martyrs to their disease, and they bespeak our kindest patience while learning the new life of self-denial.

It is not the single drug, nor any of its possible combinations; it is not the dietary alone, nor is it the out-of-door country life that may be prescribed for the epileptic, but it is the combination of them all, unremittingly carried out for years, that ameliorates the epileptic state.

Without doubt, the greatest single drug in the treatments of epilepsy is some bromide salt, and in this short paper I shall largely confine myself to remarks on this drug. There are a number of different drugs used in combination with the bromides, which have received favorable report of late, but I feel that in most instances the potent agent is the bromide, and its action is often confused by using other drugs in combination. If they are used at all, I believe they should be administered separately; and indefinite and ineffectual compounds should be discouraged, as has been done elsewhere in general medicine.

Since the introduction of the bromide salts in 1851 by Locock and McDonnell, their use in the treatment of epilepsy has had a varying fortune. Some maintain that they should be used only after all other remedies have been tried, and others claim that they are really the only remedies we have for the disease. Between these two extremes of opinion we have varying views. Undoubtedly the perfunctory administration of bromides has been productive of great harm. The train of their evil effects is too well known for me to detail them; instead, I purpose to give some personal experience with the bromide salts.

It is unfortunate that epileptics and their relatives expect physicians to give medicines at once which will lessen the frequency and severity of the spasms, because not enough attention can be paid to a careful case study of the digestive tract and its tolerance of the bromides. If the patients are anæmic and in poor physique, they must be built up while bromides are administered. Iron tonics and cod-liver oil should be given to epileptics, either to correct existing malnutrition or forestall the sedative effects of the bromides. In this adjuvant treatment, a peptonized manganese of iron and hydroleine are very good. I hold the giving of tonics in addition to the bromides as important as the diet and the general living regimen. The bromides should be given as early in the disease as possible. I use the well-known bromide formula; made with simple elixir, it contains grs. v. each of potassium, sodium, and ammonium bromide to the teasponful. This preparation is given because it is palatable and contains the dynamical effects of grs. xv. of bromide to the drachm, an easy and convenient unit to work upon in further bromide treatment. The patient should begin on one drachm a day at the outset, given night or morning according to whichever end of the day the seizures occur most frequently. This should be kept up three or four days, until the sedative power of the single dose can be determined, and then successive drachms may be added as thought necessary, until the seizures cease or 480 grs. or ℥ i. of the salt is taken. The giving of bromides of late has been in too small doses; the amount should be sufficient to stop the seizures, or it is better not to give the bromides at all. The same care and attention should be exercised in giving bromides as though in the different cases we were handling a new drug each time.

Every possible precaution toward the prevention of bromide intoxication must be taken. Unless we are prepared to give our patient every attention, bromides should never be given; their false or careless administration is disastrous to the patient. The epileptic organism must be kept in the highest possible functionating state. Hot and cold baths, massage, and electricity should be given. If the patient has a good physique, a prolonged hot bath each week should be given on retiring as a general sedative and to promote diaphoresis. Patients taking bromides should take a cold shower bath and a friction rub every morning on rising. I regard these cold baths in the morning as vital to the maintenance of the peripheral circulation when bromism presents its index.

The bowels must be watched, the diet must be prescribed; high rectal saline douches should be given once or twice each week. The mouth must be kept scrupulously clean; internal antiseptics should be given constantly to some, and to others at stated intervals. If the face shows the bromism, cloths wrung out of hot water may be applied to the face to relax the tissues and aid the circulation in re-establishing glandular activity. This skin treatment should be followed nightly for fifteen to twenty minutes; the last moist-heat application should be a hot saturated solution of boracic acid, and finally massage and sulphur or zinc ointment should be applied to the acne (a careful soaping of the face before moist heat is applied is often necessary). Acne in the pustular stage should be opened before moist-heat treatment is used. I have never seen a case of acute or chronic bromism of the skin which would not, to a great extent, yield to this treatment, when the other factors in bodily hygiene were faithfully looked after. I regard it as absurd to look to Fowler's solution of arsenic to remove any great amount of bromide intoxication.

If chronic bromism appears, small repeated doses of saline cathartics should be given every other night for a week; milk and vegetable diet instituted; Russian or cabinet baths ordered, followed by diaphoretics and twenty-four to thirty-six hours in bed. If this does not lessen the bromism, we should gradually reduce the bromides, or they may be entirely withdrawn for two or three days under close watch for paroxysmal syncope.[1] Usually no attacks will occur in a bromized epileptic if but three or four days' freedom from bromides be permitted.

Once the seizures having been stopped by large doses of bromide, the work in treating the epilepsy has only begun. The high dosage must be maintained for as long a time as possible without intoxication. Only so much bromide is effective as the tissues will absorb and hold. The longer time the dosage can be maintained without bromism the better. Usually the patient is left to himself as soon as the high dosage has

[1] The seizures or evidence of returning epilepsy after bromide treatment, are peculiar in so far as their first indication or manifestation is a form of syncope or simple loss of consciousness, resembling cardiac syncope more than the absences or vertigos of petit-mal epilepsies.

stopped the convulsions. The patient and relatives (only too often the physician) reason: the seizures have ceased, the medicines have been adjusted, and the laws of hygiene need not be so strictly enforced. From such laxity in treatment we can expect bromide intoxication to follow swiftly. The seizures are sure to occur more frequently than before, the toxicity seeming to aid the frequency of seizures once reassumed.

The medical attendant may only realize his mistake when he learns that the patient had changed physicians and the bromides had been stopped. Cases in which the care of administering bromide is neglected, form by far the greater part of those said to stand the bromides poorly. While establishing the high dosage for any particular case, the physician should see the patient two or three times each week; every day is better. At the end of a month or six weeks, after the individual regimen is thoroughly established, the patient may go two or three months without a consultation. Of late, when cases will not stand the bromide salts in high dosage, because of the resultant toxicity developed, I give a ten-per-cent. solution of bromine made up with oleum sesami. This formula is known as bromipin. This emulsion of bromine I have found both highly nutritive and sedative.

Emulsion of bromine:

℞ Gum. acaciæ gran ..... ʒ vi.
Olei sesami..... ʒviij.
Syr. simplicis..... ʒ ij.
Aquæ..... ʒ vi.
Ol. gaultheriæ..... ♏ lx.
M. fiat emulsio. Adde:
Bromi puri ..... gr. dcccclx.
S. ʒ ss. night and morning, increasing as directed.

Or it may be combined in the emulsion with potassium bromide in order that the pure bromine will not be lost by fuming, the vegetable oil being substituted by cod-liver oil.

Emulsion of bromine, modified:

℞ Gum. acaciæ gran ..... ʒ ij.
Ol. morrhuæ..... ʒviij.
Syr. simplic ..... ʒ ij.
Aquæ..... ʒ vi.
Ol. gaultheriæ ..... ♏ lx.
M. ft. emulsio. Adde:
Bromi puri ..... gr. dcccclx.
Potass. bromidi..... gr. cccclxxx.
S. ʒ ss. night and morning, and increase as directed.

Bromine given in this manner is less irritating to the intestinal tract, and is not constipating, is markedly less toxic, and seems to be much more lasting in its effects. It should be given a more extensive trial, especially when the single or polybromic mixture fails. In making the bromine preparation, the druggist needs to be quick in adding the bromine to prevent loss from fuming. In giving bromine we should consider gr. ii. by weight of bromine as equal to gr. i. of bromide salts from a therapeutic standpoint. Not infrequently after the bromide dosage has been adjusted to the seizure level, epileptics will suddenly surprise the physician by having two or three seizures just as the second phase of treatment is begun. The explanation is simply this: The patient from being a passive agent, from living a sedentary life, is suddenly placed on active out-of-door life, for the establishment of a real and permanent cure if possible. The patient's bodily activity increases the elimination of waste products, and the bromide salts are also eliminated more rapidly, consequently the seizures recur. Therefore we should add gr. xv.–xxx. to the dose in changing the patient from a sedentary to an active out-of-door life, and then readjust again as necessary. These large doses of bromides should be continued for several weeks after the seizures stop; then week by week the bromides should be reduced gr. xv. per week until the seizure level is regained, and that dosage allowed to remain to suppress the convulsions. Then, and not until then, can we consider our patient free from the active phase of his treatment. Arrangements may now be made for daily exercise, schooling, manual training, and other occupations of life, preferably in the country and at agricultural pursuits. Physical activity, at least several hours daily, should be prescribed and carried out faithfully.

Some illustrative cases, under high dosage of bromides, may be cited here. The cases were either those that had not been helped by other medication, or those in which bromides could not be given to the point of desired therapeutic effect, without a rapid and dangerous toxicity developing. The precautions in giving the bromides enumerated in this paper had never before been undertaken.

Case I.—Girl, seventeen years old; idiopathic epileptic; ordinary bromide medication had been often tried, but did not influence the seizures. She had on an average two hundred and fifty grand-mal and petit-mal attacks per month. Bromides were given according to the methods stated in this paper. The seizures were not modified until gr. cc. daily were taken; they then occurred forty times per month; the next month on gr. ccc. they numbered but four attacks, and under ʒ i. daily the attacks ceased altogether. The patient has had only five slight losses of consciousness for the last eighteen months. She is now taking ʒ ss. daily, and is in excellent bodily and mental health, has grown six inches taller in two years, and gained fifteen pounds in weight; although bromides are counted unhygienic, the seizures in this case must have been very detrimental to growth and development. Menstruation has now become regular for the first time since the epilepsy began at fourteen years of age.

Case II.—Traumatic epileptic; trephined. Epilepsy continued and all drugs, including ordinary doses of bromides, failed. Patient had twelve to fourteen grand-mal seizures per month. Bromides were gradually given until gr. cclxxx. per day were taken. The seizures ceased entirely, and have not shown themselves for six months. The patient is improving mentally and physically, is practically a new man. He takes gr. cxx. daily and shows absolutely no bromide intoxication, not even a facial acne.

Case III.—Man, twenty-six years old; an idiopathic epileptic with psychical seizures consisting of but momentary losses of consciousness, never in convulsions. Epileptic for twenty years; had never found a remedy that could affect the regular periodicity of the psychical series until placed on bromides in high dosage. He is now on gr. clx. daily, and has had no attacks whatever for over four months. There has been a very remarkable improvement physically and mentally; slight facial acne and general bromic toxicity occurred two or three times, but were easily corrected by care. No one would know by his facial or general appearance that this patient had ever taken or was now taking bromides.

I have reserved to the last to speak of what I regard as without doubt the greatest adjuvant to the bromides discovered in recent years. It is a method I am now using successfully on several epileptic patients, and which is known technically as hypochlorization or salt starvation. This method was brought forward by Toulouse last year, who reported a series of very successful trials, and more recently several continental physicians have reported favorably. Its rationale is simply that bromine can substitute chlorine in the tissues. Experiments upon dogs and cats, fed for ten days upon bromine, showed that more bromine could be procured from their remains than chlorine. In the kidneys and bone marrow, the proportion was two to one. Bromine is not a foreign substance, but a true

mineral constituent of the body; when discontinued it is replaced by alimentary chlorine, and requires about four months for its complete elimination. It is, therefore, evident that bromine may partly replace chlorine chemically and physiologically as well. Experiments upon animals show that in the gastric juice the chlorhydric acid is replaced by bromhydric acid. Thus it is seen that we have a good basis for the clinical fact that, when an epileptic is under salt starvation, the bromides are more greedily absorbed in the tissues. We can at once see how very important this method is in the treatment of epilepsy. Having established the fact theoretically, how can we carry it into practical effect? Nearly all epileptics are very fond of salt, and eat large quantities of it; I know of several patients who formerly consumed two ounces Troy per day, before the hypochlorization treatment. It is difficult to get many of them to undergo voluntary deprivation of salt, therefore a semi-starvation of salt is about all that can be expected from them. One of the best and easiest ways of carrying out this adjuvant of the bromides is the establishment of a milk diet with occasional removal to a mild salt diet. For a long time it has been known that milk is the epileptic diet par excellence, and assists in lessening the formation of toxalbumins in the alimentary tract; but a part of its value lies in the salt deprivation. To aid the carrying out of the salt-starvation treatment, I have modified Toulouse's daily dietary, so as to give the following:

Breakfast: Milk, one pint.

Lunch: Two soft-boiled eggs, farina, milk and sugar, coffee; or muffins made of eggs, farina, milk, and sugar, and coffee.

Dinner: Bouillon unsalted or chicken broth with a little rice; boiled beef unsalted or roast beef unsalted; potatoes.

Supper: Porridge made with farina, sugar, boiling milk; or milk and rice.

Gr. xx.–xxx. of table salt should be given the patient daily to use on food as desired, as this is the essential physiological amount to maintain health.

By this method we can reduce the usual amount of bromides one-half, and still get the same therapeutic result; again, we lessen the chance of bromide poisoning one-half. The economy of this method is obvious both in epilepsy and other diseases in which sedation is needed over a long period of time; sufficient has been proven from a clinical point to warrant us in giving this method extended trial in connection with the bromide treatment in epilepsy.

In conclusion I would summarize the present-day medical treatment by the bromides:

1. By a combination of diet, regular occupation, and personal hygiene, the bromides give the best results in treating idiopathic epilepsy.

2. The bromides, singly or combined, still remain our chief sedative for the epileptic state—in the young epileptic, to secure a possible entire suppression of attacks and ultimate cure of the disease; in the adult, an amelioration of frequent paroxysms and comparative physical and mental comfort.

3. The bromides to be effective in chronic and long-standing cases must be given in large daily doses to suppress convulsions, from gr. ccc.–cd. if necessary. They should be given gradually to find the sedative level, at which level it is the physician's principal duty to maintain them with physical and mental comfort to his patient.

4. Hot and cold baths, high enemas, alimentary antisepsis, and massage are absolutely essential to successful bromide medication.

5. Bromine is a worthy substitute for the bromides in many cases in which the latter are contraindicated or cannot be given in high dosage.

6. Salt starvation or semi-salt starvation is a great adjuvant to the bromide treatment, and should be thoroughly tried in all cases in which bromides or bromine are apparently contraindicated before they are discarded.

REPORT OF A CASE OF PRIMARY GLIOMA OF THE OPTIC NERVE.[1]

By REDMOND W. PAYNE, M.D.,

SAN FRANCISCD, CAL.,

SURGEON TO THE CALIFORNIA EYE AND EAR HOSPITAL; CONSULTING OPHTHALMOLDGIST TO THE SOUTHERN PACIFIC HOSPITAL.

History.—The patient was a girl baby two and one-half years of age, apparently healthy and well nourished. There was no family history of malignant growths, and, so far as could be made out, no specific history. The right eye began to "turn in" a few months after birth, and exophthalmus began about one year later and increased gradually until the lids could not be closed over the globe. At the time of operation the eye was turned strongly inward and upward so that the cornea was half covered by the internal canthus. There had been but little if any pain. The child was under observation for several months, and when first seen nothing could be felt in the orbit at any point, even with the patient under an anæsthetic. Pressure upon the globe directly backward met with resistance. The child appeared to have but little if any vision. The pupil appeared normal in size, but reacted sluggishly. The fundus showed the remnants of an old papillitis. The eye could be turned almost to the median line outward, but scarcely at all downward. One week before operation upon palpating the orbit I felt a small resistant body the size of the end of the little finger on the temporal side of the globe.

Diagnosis.—As the tumor had grown very slowly and there had been no pain, it was thought to be benign, to be within the muscle funnel and pressing upon the nerve.

Operation.—The patient was sent to the California Eye and Ear Hospital, where I operated with the assistance of Dr. L. C. Deane and in the presence of Dr. Callandreau, the family physician, Dr. Hulen, Dr. Schloss, and Dr. Cohen. The external canthus was laid open widely and an attempt made to dissect out the tumor and leave the eye. This was impossible, however, as the resistant body I had felt was found to be the nerve turned out in the form of a loop (as shown in Fig. 1), and as the sheath was followed back it was found to enclose the tumor, which lay across the middle of the orbit. More or less of the side and back of the tumor were bound by connective tissue to the posterior nasal wall of the orbit, and the nerve seemed pinched off at the foramen. The patient made a good recovery, and since the operation seven months ago has been in excellent health.

The Tumor.—As shown in Fig. 1, the tumor is confined within the sheath of the optic nerve and has been removed close to the optic foramen. Microscopical section shows the nerve tissue to be entirely destroyed and its place taken by the glia cells (as appears in Fig. 2). These facts strongly suggest that some of the cells may have passed into the nerve within the cranium. This is also the opinion entertained by the pathologists who have made sections of this tumor, Drs. Pillsbury, Montgomery, and Canny; they also agree in regarding the tumor as a pure glioma of the nerve.

Prognosis.—What prognosis are we to give this patient? Is such a neoplasm, springing from the neuroglia of the nerve, benign or malignant?

[1] Read before the San Francisco Society of Eye, Ear, Nose and Throat Surgeons, June 21, 1900.

As these cases are rare, not many of us can base a prognosis on their personal experience and observation, but must go to the literature upon the subject. Here one finds a great amount of confusion and conflicting opinion, as the question is considered by the general pathologist or the ophthalmologist.

In order that we may better understand the question presented, it might be well to make the following general statements:

First. Let us understand from the outset that by the term malignant is meant "a constant tendency to local relapse and to the development of metastases."

Second. In the generally accepted classification of tumors but two forms are malignant, the sarcoma and the carcinoma.

Third. As to the special classification of optic-nerve growths the following is the clearest:

(*a*) Those springing from the dural sheath are sarcomata.

(*b*) Those springing from the pial sheath are endotheliomata.

(*c*) Those springing from the neuroglia are gliomata.

It will be seen in both the general and special classification that true glioma is indicated to be a benign tumor. There is but one exception to this rule, viz., glioma of the retina, which is very malignant.

Taking, then, the subject of glioma of the optic nerve and looking into the literature upon the subject we find that Stengel regards glioma of other parts than the retina as essentially benign, and says it is dangerous mainly on account of the pressure it exerts, after the manner of a fibroma; that sarcomatous transformation is exceedingly rare. In his "Maladies des Yeux" Meyer states that tumors of the optic nerve are rare, but he considers three principal forms: myxoma, glioma, and glio-sarcoma. He considers the first two benign. Charles K. Mills, in his "Diseases of the Nervous System," says gliomata develop from the neuroglia of the brain tissue, while the majority of brain neoplasms originate in the membranes, vessels, and glands. The hard varieties are closely allied to fibromata. According to the preponderance of their

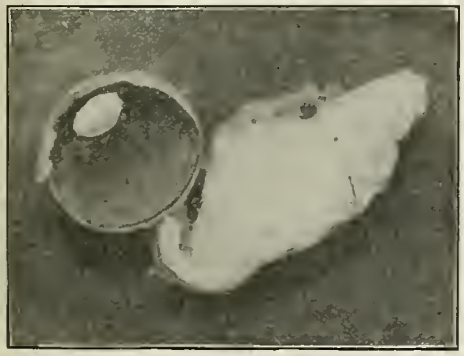

Fig. 1.

constituent tissues, sarcomata are classified as fibro-sarcoma, glio-sarcoma, etc. Here again glioma is implied to be benign and to be malignant only when sarcomatous tissue is present. J. Schobl, in his article in Norris and Oliver's system, states that primary tumors of the optic nerve are extraordinarily rare; but nothing is said about the prognosis of such cases, nor about how they are to be regarded. It would appear, however, that not many primary gliomata of the optic nerve have been reported. In *The Lancet* of October, 1898, Buller and Marshall report a case of glioma of the optic nerve. They collected one hundred and thirty cases of optic-nerve growths. Although they favored classing all such growths as malignant, in not one of the cases reported was there a local relapse or the development of metastases. Hence it would appear that this is an incorrect position to take. Virchow says diffuse hyperplasia of the neuroglia produces hypertrophy of the organs concerned, while circumscribed hyperplasia forms gliomata.

Neuroglia is found in the brain, medulla, retina, acoustic and other cranial nerves, and the suprarenal glands. Gliomata are found wherever neuroglia is present normally, and it appears from the authorities

Fig. 2.

quoted that it is a benign tumor, except when found in the retina.

From both the general and special classifications of tumors one finds that when they spring from the sheaths of the optic nerve they are likely to be malignant, while those springing from the neuroglia should be classed as benign.

It would appear, then, that true glioma, in all other parts than the retina, is essentially benign, in the opinion of nearly all pathologists, and that primary glioma of the optic nerve, springing from the neuroglia as it does, should be regarded in the same light as glioma affecting the brain, cord, and cranial nerves, where it is conceded to be a benign tumor, *i.e.*, a circumscribed hyperplasia of the neuroglia. It is to be considered dangerous only on account of the pressure it exerts.

I find two opinions, however, which imply that such growth of the optic nerve might be considered malignant, viz.: Senn says that sarcoma of the neuroglia of the central nervous system is called glioma—it is the most frequent of all brain tumors, is very vascular—a soft tumor with slow growth, and with a more benign course than sarcoma. This is an exceedingly general statement by Senn and a classification peculiarly his own.

In speaking generally of orbital growths, Knapp says tumors of moderate malignancy, fibro-sarcoma and epithelioma, also those of great malignancy, as glioma and small round-celled sarcoma, furnish a justifiable indication for the removal of all contents of the socket. This statement also is a very general one, and though he implies that primary glioma of the optic nerve is to be classed as malignant, I believe the statement is intended to cover such gliomata as extend from the retina.

Our case, then—a primary glioma of the optic nerve—would seem to carry a good prognosis. If the tumor is of the nature of a fibroma, as seems conceded, it is probable that the few cells which may remain within the sheath of the nerve beyond the optic foramen may undergo degeneration and absorption, as the small remnant of any other benign tumor would, under like

circumstances. In the light of the foregoing opinions the tumor is certainly not to be considered as a truly malignant one.

Discussion.—In the discussion which followed the reading of this paper Dr. V. H. Hulen said he had seen the patient before the operation, and, considering the nature of the tumor and its occurring in a child, he believed the prognosis absolutely bad; that probably within a short time, perhaps a year or two, it would prove fatal. He had seen a number of such specimens, but the one presented was the finest one. He wished to know how it was mounted.

Dr. L. C. Deane, who was present at the operation, considered the case an exceedingly unusual one, and wished to say that in the description the writer had failed to mention that when reaching back to divide the nerve he had found it already parted, as he has said, pinched off at the foramen. This being the case, Dr. Deane believed the tumor cells must have extended into the cranial cavity and that we probably must expect a future development in the brain.

Dr. Robert D. Cohen, on the contrary, believed that in the absence of personal experience in a case so rare as the one shown, we should be guided in forming a prognosis only by those who have had such experience, and in this light he believed that the writer was correct in refusing to consider the prognosis entirely unfavorable. The fact that, clinically, retinal glioma is a malignant growth, whereas, according to the majority of reports, primary glioma of the optic nerve is benign, corresponds to the well-recognized fact that histologically the two types are dissimilar. As to the benign character of optic-nerve growths in general he referred to Vossius, of Giessen, who goes so far as to say that recurrence is rare even after incomplete extirpation.

Dr. Hulen considered, however, that although the data and opinions submitted by the writer raised several questions, the prognosis must necessarily be considered bad, if we are to judge from the description given that some part of the growth had extended into the cranial cavity.

The writer, however, believes that, as these tumors are exceedingly rare, we must base our opinions upon the experience of those who have seen such cases. According to the classification of pathologists, this tumor, springing from the neuroglia of the nerve as it does, is to be classed as a pure glioma. It should, then, be regarded in the same light as glioma affecting the brain, cord, and cranial nerves, where it is conceded to be a benign tumor, more of a fibroma type than of a malignant type. Considering the opinions presented, the tumor certainly did not impress him as a malignant one, and though of course it might possibly continue to enlarge within the cranium, he did not believe it would do so in more than a circumscribed manner.

THE CHOICE OF SUTURE FOR THE PATELLA.

By EDWIN M. COX, M.D.,
NEW YORK.

The consensus of opinion among surgeons of the present day is that the best treatment for fracture of the patella is by operation and suture, but in expressing this opinion the reservation is usually made that other forms of treatment involve a smaller proportion of accidents of all kinds, unless the operator is one who is thoroughly accustomed to the routine practice of aseptic precautions, and is able to command practically perfect facilities for operative work. There are some differences of opinion as to the details of the operation, such as regard the method of washing out the joint, but the majority of writers agree in recommending the use of silver wire for suture material in the fractured bone. While some of the arguments advanced in favor of this suture are no doubt valid, certain others, it seems to me, are founded on fallacious views. It is certainly true that silver wire is strong and easily made sterile, and that properly placed in the fractured patella it will hold the fragments together, and it is also true that many cases have been operated upon with good results after the use of this kind of suture. However, the entire non-absorbability of the wire is a decided objection to its use, and in spite of the fact that many patients have been thus operated upon and are now carrying the wire without any evidences of irritation, we cannot possibly be certain that all will continue to do so indefinitely, and until we are certain that no patient will need to have the sutures removed and possibly a scraping operation done for localized caries, we must admit that the principle of using silver wire is defective, though the practice is apparently attended with much success. The fragments in an average case of fracture of the patella do not require to be held together with great firmness, and a forcible tying of metallic sutures to some extent defeats its own purpose. Those who recommend that wire sutures in this bone be drawn tight, twisted, thus increasing the tension, and the ends then hammered down, seem to consider that living bone behaves like an inanimate solid substance and can be treated much as a carpenter would treat a block of hard wood. This is a decidedly fallacious view, for living bone is an exceedingly vascular structure, and needs a large amount of blood for its physiological functions, which, when disturbed, speedily show pathological effects in the bone. A wire suture drawn tight in bone can cause a local pressure necrosis and absorption until the tension is relieved just as certainly as in soft tissues, and the well-known promptness with which tight sutures of all kinds cut through soft tissues needs no comment. It is a mistake to suppose that great tension is required to hold a fractured patella properly in place, because when once the fragments are in position and the splint is carefully applied, the fragments will not be pulled apart by the quadriceps extensor, which is not acting at all unless voluntary efforts are made to raise the foot, and these efforts need not occur. Silver wire is objectionable in the patella, as elsewhere in the body, because it is non-absorbable and may cause trouble; because it induces the operator to exert undue tension when the sutures are tied, and causes him to rely too much on mere strength in the suture; and because absorbable sutures are available, to which these objections are not applicable. The idea of the operation of suturing the patella should be to hold the fragments in apposition until natural processes of healing can begin, and also to prevent displacement when the dressing is applied at the operation. Movements, violent enough to break a good catgut suture, should not be allowed to

occur after the suturing has been done. At the end of twelve or fourteen days, when the first change of dressing is usually made and moderate lateral massage begun, there is practically no danger of separating the fragments so long as flexion is avoided and the leg is supported at the heel. The three following cases, one of them previously reported among several others,[1] will illustrate the results after the use of catgut sutures, in the first of which the material was prepared by the ether-alcohol-bichloride-of-mercury method, and in the others by the formalin method.

Case I.—Boy, aged about fifteen years, fell five stories and apparently struck on one knee. He was brought to Roosevelt Hospital with a compound comminuted fracture of one patella, a simple fracture of the femur on the same side, and a simple fracture of the tibia and fibula on the other side. There were no other injuries; the general condition was good. I operated the same evening, opened the knee joint by a free transverse incision, washed it out with hot surgical salt solution, removed several fragments of the shattered patella, and sutured those remaining, with moderately heavy catgut. The plaster-of-Paris dressing was removed at the end of two weeks, and very moderate massage begun, laterally. Recovery was uninterrupted, and at the end of nine months, at which time the patient was seen for the last time, the movements and functions of the knee joint were normal and perfect in every particular. Callus had almost obliterated any palpable traces of fracture in the patella. This boy had walked out of the hospital at the end of ten weeks.

Case II.—A priest, aged thirty-eight years, was brought to St. Francis Hospital on June 20, 1899. Six days previously he had sustained a simple transverse fracture of the left patella in the usual way by indirect violence. The joint was much distended. I operated the next day by transverse incision, and cleared the joint of the clots with the usual hot salt solution. The cleanly divided fragments were united by two formalin-catgut sutures of moderate size, used double. The flap of the aponeurosis covering the front of the bone had fallen between the fragments and was so tightly adherent to the fractured surface of the upper one that it had to be scraped off. The plaster-of-Paris dressing was changed in two weeks and very moderate lateral massage commenced. This was from time to time increased in extent and variety in spite of the timidity of the patient, and improvement progressed rapidly. He was last seen fourteen months after operation, when his joint was found absolutely normal in every respect. A slight notch can be felt in one edge of the patella; otherwise it is exactly like its fellow.

Case III.—Woman, aged about thirty years. Operated upon by me at St. Francis Hospital June 21, 1899, for simple fracture of the patella sustained four days before. The conditions were almost exactly those of the previous case, and the treatment was exactly the same. Recovery was even more prompt than in Case II. and at the end of eight weeks she walked home and returned only once or twice to exhibit herself. When last seen, about twelve weeks after operation, the functions and movements of the joint were almost perfect, and the patella, as far as palpation showed, was as if it had never been fractured.

These cases are only illustrative and naturally have not the value of a large amount of statistical evidence, but such results certainly show that the absorbable suture can be used successfully for holding the fragments of a broken patella, and it can hardly be denied that, other things being equal, an absorbable suture has advantages over one which is metallic. On these cases the catgut used was not hardened in any way in order to delay absorption, and such a precaution does not seem necessary, though there would be no objection to its employment. A matter of great importance is the application of the plaster-of-Paris splint during the first few weeks, so that moderate pressure shall be exerted above the patella. During the changing of the dressing great care should be exercised to prevent accidental strains reaching the sutured bone. It is best to support the leg from the heel, and to make the patient keep his body quiet at the time when the dressing is being done.

[1] Annals of Surgery, December, 1895.

Two Cases of Hysterical Hiccough Cured by Etherization.—Alfred Poastena describes two cases, the first that of a young married woman of neurotic taint and history, who had hiccoughed for three months as a result of a mental shock. None of the usual remedies having given relief, the writer gave the patient ether for about three minutes, which brought about a complete cure. The second patient was a young girl, also of neurotic family and personal history, who had hiccoughed for twenty days. Etherization caused an immediate cure. The writer believes the result to be due, not to suggestion, but to the action of the ether, which removes the brain from the influence of a fixed idea.—*Gl' Incurabile*, October 1 and 15, 1900.

The Treatment of Phagedæna.—C. F. Marshall gives a résumé of three cases reported in *La France Médicale*, April 14, 1899, by Jullien, who pins his faith on injections of calomel. In the first two cases the condition became worse after the calomel injections; in the third case a cure took place, but probably occurred in spite of the treatment. Marshall urges that mercury is a dangerous remedy to use in all conditions of phagedæna. He believes that as in these cases there is a secondary local infection caused by pyogenic cocci, this ought to be treated primarily, mercury being held in reserve till after the sore has healed, and used even then only in case of the appearance of secondary syphilis. The treatment, then, must consist first in the energetic local disinfection of the sore, which is best attained by the warm antiseptic bath. The writer prefers iodine in the form of a glycerin solution of iodine in iodide of sodium. The strength should be about 1:5,000. In the intervals between the baths the sore should be powdered with some non-irritating powder, such as airol or calomel and zinc. The local treatment must be combined with good feeding, port wine or burgundy, and tonics such as quinine. To treat a case of phagedæna with large doses of mercury is simply to add another poison to the system. The primary affection is essentially pyogenic and not syphilitic, though such sores usually occur in connection with syphilis.—*Treatment*, November, 1900.

The Mortality and Morbidity of Physicians.—Alfred Moeglich has collected a series of statistics which give results sufficiently discouraging to the medical practitioner who aspires to reach the scriptural age of threescore and ten. Of all the professions, medicine offers its devotees the least promise of a ripe old age; the average time of death varying from fifty-two to fifty-six years, according to different authorities; while for the clergy, for example, it is ten years later. The combination of pedagogy with medicine appears to be particularly fatal, for one set of figures in which the normal death rate is represented by 100 gives 111 as the factor for physicians, and 113.8 for medical instructors. Of the causes of death infectious diseases rank highest and, among these, typhoid fever occupies so prominent a place as almost to entitle it to char-

acterization as an occupation disease. Tuberculosis comes next, the death rate from this cause among physicians being almost double that of the clergy. Altogether it is rather a melancholy fact to realize that the men whose life work it is to teach others how to keep their health or to regain it if lost, should themselves be unable to profit by their own knowledge and should be so completely at the mercy of the great bodily and mental stress to which their calling subjects them.—*Deutsche Aerzte-Zeitung*, November 15, 1900.

Reptilian Delusions.—W. v. Bechterew describes several instances in which the patient was possessed of the singular delusion of having swallowed some reptile which had taken up a permanent habitation in his interior and was causing its host unbearable pain and anxiety through its movements. When the parasite in question is supposed to be a snake the usual theory is that the patient, who is most often of the lower classes, swallowed the animal while asleep out of doors, the details of the awakening with the sensation of the descent of the cold clammy body being given with graphic distinctness. When the invader is thought to be a frog or lizard the explanation is more simple, for it is a matter of common belief among country folk that the spawn of these animals, swallowed in the drinking-water, undergoes its cycle of development in the stomach, and is sometimes even secretly administered in this way with malicious intent. The bearer of such an amphibian invader complains of the pain and disturbance its movements produce, or of its gnawing away at his vitals, or even annoying him by the emission of characteristic croaks or hissings at untoward moments. The delusion rests on the unconscious exaggeration of normal or slightly increased gastric sensations in predisposed persons of hysterical temperament.—*Centralblatt f. Nervenheilkunde und Psychiatrie*, November 19, 1900.

The Use and Place of Caustics in the Treatment of Malignant Diseases.—S. B. McGavran believes that caustics should not be used in the treatment of cancer of the breast, uterus, tongue, tonsils, eyelids, orbit, penis, scrotum, and rectum. Cancer of the lip should be treated by early excision. But epithelial cancer of the nose, cheek, forehead, and neck can be cured by the timely use of caustic agents judiciously and properly applied. Weak caustics, as nitrate of silver and mineral acids, should never be employed. Caustic potash, cloride of zinc, and arsenious acid are the three agents that have given the best results. Cases must be treated energetically. During the application of the caustic a hypodermic of morphine should be given every five or six hours if there is much pain. Some patients say the treatment is painless.—*The Columbus Medical Journal*, November, 1900.

The Action on Heart and Respiration of the Distillate from Tea and Coffee.—C. Binz made numerous experiments on a healthy adult and on dogs, and finds that the stimulating properties of tea and coffee, as they are usually prepared, depend partly on the caffeine and partly on the volatile substances present, the caffeine contributing the major share of the physiological effect. It was found that these volatile bodies when obtained by distillation and free from caffeine produced a well-marked increase in the respiratory capacity, which effect was especially great if no food had been taken for several hours previously. This stimulation was of only short duration, and was due to an increase in frequency and not of depth of the respirations, while at the same time slight muscular unrest and psychical excitement were produced. The pulse rate was not altered.—*Centralblatt für innere Medicin*, November 24, 1900.

Pretuberculous Splenomegaly.—Gabriele Tedeschi has observed a number of prisoners, who at the beginning of their term were in good health, but later developed enlargement of the spleen, as well as others who, having splenomegaly, became tuberculous later. The author does not believe that either prison diet or hygiene is at fault, but thinks that the close association of persons whose lives are such as to prevent resistance to infection, together with the prevalence of tuberculosis in prisons and its contagiousness, account for its frequency. Experiments with Koch's tuberculin have convinced him that the splenic enlargement is, in these cases, a primary tuberculous manifestation, leading later to a well-defined clinical form of tuberculosis. These results have been reached by the use of Koch's first, not his latest, tuberculin.—*La Riforma Medica*, November 15 and 16, 1900.

Pregnancy and Tuberculosis.—Samuel Bernheim believes that even in predisposed individuals pregnancy does not necessarily excite tuberculosis. The danger is greater if the patient be very young. If the tuberculous lesions are extensive, as in miliary tuberculosis, death is almost inevitable. Multiple pregnancies are disastrous in predisposed subjects. The lying-in period is specially fraught with danger for consumptives, and the physician must be constantly on the watch. Nursing must be forbidden, as it is too great a tax upon the strength. In any case in which tuberculosis is aggravated in the early weeks of pregnancy, the physician is justified in inducing abortion. The influence of paternal tuberculosis on the course of pregnancy is *nil*. Immediately after labor, measures must be taken to protect the new-born infant from contagion, and to place it in hygienic surroundings.—*L'Union Médicale du Canada*, November, 1900.

A Case of Double Intra-Ligamentous Cyst.—C. Jeff. Miller describes a case, and says that as a working-rule it may be safely stated that in many cases where intra-ligamentary growths are suspected, it will be best first to secure the uterine artery or arteries through the vaginal vault before opening the abdomen. If cysts of considerable size are found occupying both broad ligaments and intimately connected with surrounding structures, hysterectomy as a routine measure will yield the most satisfactory results. If sepsis is present, *e.g.*, badly adherent pus tubes, or an infected cyst sac, drainage is of utmost importance, and is best obtained per vaginam by removing the uterus, unless very good reasons exist for retaining that organ. Drainage is oftener indicated than in other pelvic conditions, owing to the extensive raw surfaces produced during the enucleation of the growth and the notable tendency of these growths to become infected.—*New Orleans Medical and Surgical Journal*, November, 1900.

The Practitioner's Duty in the Treatment of Acute Intestinal Obstruction.—A. Ernest Maylard discusses the diagnosis of this often puzzling disease. One thing is certain—when the group of symptoms known as "peritonism" is present, the abdomen must be opened. It is of course proper for the practitioner to endeavor to discover the true cause of the peritonism which is doubtful and obscure, but if any such endeavor is to entail delay, or a waiting for the manifestation of more pronounced and distinctive symptoms, then the attempt will not only be possibly useless but harmful. Every hour lost in attempts to find the cause when the condition itself is known to be critical tends only to lessen the chances of effectual treatment by early operative intervention. Most surgeons will be obliged to confess that in their experience in the majority of cases of acute intestinal obstruction, the true cause is not discovered until after the abdomen is opened.—*The Practitioner*, November, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, January 12, 1901.

THE DUTY OF THE STATE IN THE CARE OF THE INSANE.

SINCE insanity has come to be looked upon as a form of disease and not as a dispensation from an unknowable power, the questions of its prevention and cure have received earnest and increasingly successful attention. In order to apply intelligently the principles of prophylaxis it is essential to have a knowledge of the etiological factors. Heredity is probably the most important of these, while alcoholism and syphilis come next, together with other intoxications and infections. To these influences, it is worth emphasizing, is attributable a large share in the causation not alone of insanity but of other grave diseases of the nervous system as well. It is well known, and if it is not a little investigation will soon show, that alcohol is, besides, responsible for not a small proportion of crimes committed. The same evil results may be brought about by excessive or habitual indulgence in other drugs, such as morphine, cocaine, chloral, ether, etc.

In view of all the circumstances, therefore, the State falls under certain obligations, as well to the unfortunate victims of a disease destructive of responsibility and to their families, as to society at large. Some phases of this complex subject are discussed at considerable length by Prof. Emil Kraepelin, of Heidelberg, in an interesting communication translated by Dr. Stewart Paton and published in the *American Journal of Insanity* for October, 1900, p. 235. It becomes one of the duties of the State to control by proper restriction the sale of all such dangerous substances as have been mentioned, and also to exercise supervision over those addicted to their excessive or habitual use; as well as to take the necessary steps to prevent the dissemination of syphilis and other infectious diseases. Great good can be accomplished further by improving constantly the provisions for the care of the insane; by intelligent classification, nursing, and treatment; by legal control of their reception, detention, and discharge, as well as supervision of their management. In this way not only the interests of the patient but also those of science would be best subserved. These principles are applicable in a general way both to public and to private institutions, and the necessity for their observance in the latter cannot be gainsaid.

It is pointed out that, as a rule to which there are few exceptions, the insane patient is better off, with regard to both his own welfare and that of others, in a properly conducted special hospital than in his own home or elsewhere. By proper restraint of the insane, further, the baneful influence of heredity would in some degree be minimized, as the patient would be prevented from propagating his kind. The reception, as distinguished from the detention, of patients in hospitals for the insane should be simplified to the greatest possible degree consistent with security. Insane criminals should receive treatment demanded by their disease, and with which punishment for their offences should have nothing to do.

A sharp distinction is made between the psychiatric clinic and the hospital for the insane, to the former of which only it is believed a professor of psychiatry should be assigned, while the latter must be under the control of a medical director not engaged in teaching. In the selection and promotion of physicians in hospitals for the insane it is thought that preference should be given to the ablest and most industrious men rather than to those of longest service merely. A plea, finally, is made that these physicians should be adequately remunerated by reason of the difficult, thankless, and responsible task imposed upon them.

OPIUM TAKING IN ASIATIC COUNTRIES.

THE rabid opponents of the habit of taking narcotics wax especially warm when discussing the evil effects that opium taking exerts upon the native population of India. In connection with this subject Dr. H. M. Dawbarn, professor of surgery, New York Polyclinic School, and surgeon to the City Hospital, contributes to the *Therapeutic Gazette*, November 15th, an extremely readable paper. The article in question treats of an evening spent at the Authors' Club, New York, in the company of Rudyard Kipling, and gives some of that distinguished writer's views on the use of opium in India. It may be urged that Kipling has no special qualifications to pose as an authority, but when his wonderful powers of observation are considered and when the fact is also taken into account that for many years he lived in the midst of the native population of India, it must be admitted that his expression of opinion is at least worth pondering on. Dr. Dawbarn was naturally somewhat surprised that the author of "The Gate of a Hundred Sorrows" and the "Building of the Bridge" did not denounce in scathing terms the rapacity of those in high government positions who are responsible for the general usage of the deadly drug throughout the Indian continent. On the contrary, Kipling defended the action of the authorities in promoting the production and sale of opium, and averred that it was in most instances the friend, and in certain ways the mainstay, of millions there among the natives. He said that there was an admitted difference between races in their reaction to its habitual use. A native takes it increasingly up to a certain point, and does not then, as a rule, go beyond this for the rest of his life, in the

same way as the great majority of white men use tobacco. But the white habitué of opium generally does not stop. He steadily increases his dosage until a wrecked life is the result. Kipling further went on to claim as an indisputable fact that in India the native regular eaters of opium were strengthened thereby for arduous labors; and, more important and striking as a statement, he asserted that these men were comparatively free from the fever of the country—a severe and prostrating form of malaria. He also ventured the opinion that opium was effective in treating the fever. Although, of course, Kipling's evidence cannot be regarded as that of an expert, it curiously agrees with the conclusions reached by the most eminent medical members of the British Opium Commission of 1893. Sir William Moore, a witness before the commission, said that "if taken in sufficient quantity, opium is deleterious, but this is not the use but the abuse of the drug. Opium enables people to do with less food than they would otherwise require. The same might be said of tea. The consumption of crude opium is certainly injurious, as it lessens both the secretions and movements of the stomach." As to the incidence of opium smoking on the death rate he quoted statistics of an insurance office to show that the habit did not increase the number of claims advanced by the survivors of insurers. The most interesting point brought forward in Dr. Dawbarn's comments on Kipling's views is as to whether opium has a beneficial effect on aborting or checking malarial fever. It appears that the late Alonzo Clark believed that a combination of opium and quinine was much more likely to cure malarial fever than quinine alone. Dr. William F. Arnold, surgeon of the United States navy at New Chwang, China, during the Chino-Japanese war, observed the prophylactic properties of opium in malaria, of which it is said the Chinese themselves are well aware. Prof. William H. Thomson, of New York, has called attention to his experience with certain ugly cases of continued fever of irregular type in soldiers of our army returned from Cuba and seen by him in his service in Roosevelt Hospital. These patients were not cured by either quinine given in large doses, or the use of Warburg's tincture, or by other customary remedies; but they recovered soon after being put upon the rather free use of paregoric with quinine in very moderate dosage. Dr. Dawbarn also points out that Sydenham recommended vinum opii as an effective remedy for malaria, which in his time was a common malady in Great Britain. Very many medical men who are practising or who have practised in India, have recorded views identical with the foregoing. A closer investigation of this phase of the matter might disclose truths which would be of infinite use in the treatment of intermittent fevers. No one will be found bold enough to dispute the assertion that the opium or morphine habit is degrading and debasing in nearly every instance when practised by a member of the white race, but "per contra" it would seem, judging from the mass of evidence, that the bad effects of opium taking among the people of the Far East has been exaggerated and not only does not invariably end disastrously, but is frequently poductive of good results. The reasons are probably to be sought for in the difference in temperament and constitution of the Asiatic races, as well as in the fact that by the use of the drug through several generations they have acquired a considerable degree of immunity to its harmful action. Opium is tolerated by them in the same way as are tobacco and alcohol by the Caucasian peoples, and when its consumption is not carried to excess it will not injuriously affect their health to a greater extent than will tobacco and alcohol when used injudiciously by the white man. Doubtless persons are better without opium in any form, as a rule, just as they are better without alcohol or tobacco; but conditions and circumstances alter cases, and there is, as Sam Slick wisely remarked, a great deal of human nature in man, who refuses to be made good after a pattern and cannot be induced to relinquish his "pleasant little vices" by prohibitory laws. The advocates of temperance lose ground by the intemperance of their language and by their well-meant but often indiscreet efforts to convert to their own opinions those who think otherwise. The London *Lancet*, October 27th, administers a well-deserved rebuke to those who endeavor to gain followers by advancing statements supported by no precise data, and declare that it would be better for all purposes if a paper which contains only the most general assertions were elucidated by verified details; lacking these, its value cannot be estimated or even recognized. Dr. Dawbarn is to be thanked for bringing forward Kipling's opinions on the use of opium in India, for however sceptical scientific men in this country may be with regard to their validity, nevertheless his remarks may arouse renewed interest in the question and tend to clear up the whole problem.

LIFE INSURANCE AND CARDIAC DISEASE.

Dr. F. G. Finley, assistant professor of medicine and associate professor of clinical medicine, McGill University, Montreal, treats of this subject instructively in a recent number of the *Montreal Medical Journal*. So great importance is not attached by many insurance companies to certain heart sounds as was formerly the case. The fact is now generally recognized that a cardiac murmur does not at all times betoken the existence of grave cardiac disease. Consequently a large number of insurance companies give much greater latitude to this class of clients and are willing to insure selected cases of cardiac disease, provided that certain conditions are complied with. Dr. Finley in his paper discusses various forms of heart affections from the prognosis point of view, and states that acute rheumatism is the most fruitful cause of damaged hearts, and is probably responsible for a third of such examples. Therefore, it is not surprising that insurance companies are extremely chary of accepting applicants who have recently suffered from the disease, particularly when it is remembered how often recurrence and fresh damage to the heart may ensue. Excessive indulgence in alcohol is looked upon as sufficient cause for rejection in the instance of the majority

of applicants, leading undoubtedly to hypertrophy and dilatation, often with degenerative changes in the heart. Sex also must be regarded as a factor of some importance in prognosis, women standing heart disease better than men, owing to their greater abstemiousness and less active lives. So far as station in life is concerned, the well-to-do are more favorably situated than those who have to live by the work of their hands. Writing of all forms of cardiac lesions, Dr. Finley says that after compensation has once definitely broken down, the tenure of life is insecure and uncertain. According to N. S. Davis, the average period of duration of life, after compensation began to fail, varied from 2.6 years in mitral regurgitation to 3.8 years in aortic stenosis, the figures for mitral stenosis and aortic regurgitation being between these extremes. Both Broadbent and Balfour place the average duration of aortic regurgitation, after signs of failing compensation have set in, at four years. With regard to the acceptance of cases for life insurance in which there is judged to be organic disease, much discrimination is required. The writer of the paper referred to declares that it is in valvular lesions that the chief problems in connection with life insurance lie. Serious lesions at the aortic valve are usually due to regurgitation, and the tendency to sudden death in this form of heart disease is in itself sufficient reason to reject all applicants with aortic regurgitation. Aortic stenosis is, except when occurring in advanced life, a rare disease, it being a common mistake to regard systolic murmurs in the aortic region as depending on stenosis. Lesions of the mitral valve are usually regarded as less serious than those of the aorta. There is little fear of these causing sudden death, and when such an accident does occur it is almost invariably preceded by a long period of failing. Whether mitral regurgitation or mitral stenosis is the more serious, is a question which has been by no means definitely settled in the opinion of experts. Osler is inclined to regard regurgitation as being almost as serious as stenosis. Oliver regards regurgitation as the more serious lesion, while N. S. Davis states that the average duration of compensation in regurgitation is 5.1 years and in stenosis 9.5 years. Dr. Finley thus sums up: "The class of cases which an insurance company is safest in accepting are those of mitral regurgitation and aortic direct murmurs in which secondary changes in the heart are slight or absent. Cardiac symptoms, particularly dyspnœa on exertion, should be excluded by the personal observation of the examiner, and as far as possible all cases excluded in which the lesion is likely to be progressive. Recurring rheumatic attacks exert a most unfavorable influence from further attacks of endocarditis or pericarditis. A station in life not involving manual labor and early adult life, at which period arterial sclerosis is unlikely to be present, are further elements which must be weighed in the acceptance of such cases." The present policy of life insurance companies in accepting the slighter forms of heart disease is an enlightened one. The fact must also be borne in mind that these companies protect themselves from incurring heavy pecuniary losses by limiting the insurance to a term of years, by adding an increased premium, or by a system of liens. Thus those persons who are subject to murmurs or cardiac lesions of a slight nature are able to avail themselves of the benefits of insurance, while at the same time the risks undertaken by the companies are reduced to a minimum.

THE PHILADELPHIA MEDICAL JOURNAL.

We regret to learn that Dr. George M. Gould has been discharged from the editorship of the *Philadelphia Medical Journal*, a periodical established by himself and some other Philadelphia gentlemen three years ago. The following editorial was written by him for the issue of his journal of December 29th, but was suppressed by some one who had more control over the editorial columns than the editor himself. We insert it here at Dr. Gould's request:

"A Personal Word from the Editor.—Just as the last forms are going to press, I learn that the present number of the *Philadelphia Medical Journal* will be the last (except as to the Original Article Department of the next issue) for which I shall have editorial responsibility. I am unable to set forth the reasons why the board of trustees no longer wish my services as editor. I am in complete ignorance what such reasons may be. I have heard of no criticism upon their part of my conduct of the journal, and my communication, handed to the board in session on December 8th, expressing my desire to be retained as editor, has not been answered.

"To the thousands of friends, to all subscribers, who may read these lines, I can only here express my most profound regret at the sudden separation. In the endeavor to aid in establishing a great independent medical journal, utterly free from publishers' influences, from commercial bias, and from what is, if possible, still worse, an unprofessional spirit within the profession, I have given my labor and my life, all too freely. What mistakes I may have made, I trust may be excused in the belief that they were due to a sincere desire to devote every line of the reading columns to the cause of professional truth and honor."

If those who ought to know the facts are correctly reported, Dr. Gould is no longer nominal editor of the *Philadelphia Medical Journal* (he seems never to have been editor in fact, since there was a higher authority, which could at will suppress his editorial utterances) because he failed to accomplish the impossible. Any one with a knowledge of the cost of paper and printing and possessing an elementary arithmetical training could have foretold from the beginning—and many did foretell—that the journal could not be made to pay its expenses at the price for which it was sold. Yet the trustees appear to have looked to their editor to win for the journal a circulation which would insure, not only that there should be no annual deficit, but that they should actually receive a fair return for their investment—just like any "sordid lay publisher." And speaking of "money-grubbing publishers," it is a curious fact that Dr. Gould has been discharged much more summarily by the medical men who constitute

three-fourths of the board of trustees of the *Philadelphia Medical Journal*, and who loudly proclaim that theirs is "a journal for the profession, of the profession, and by the profession," than he was some years ago by the lay publishers of the *Medical News*.

We have heard that Dr. Gould purposes establishing a new journal in which to continue his missionary efforts so suddenly arrested by his professional confrères, and we trust, in the interest of the gaiety of nations, that this rumor may prove to be true.

The new editor of the *Philadelphia Medical Journal* is Dr. James Hendrie Lloyd, who states in his salutatory that he has been from the beginning a frequent contributor to the editorial pages of the journal. Dr. Lloyd has also done creditable literary work over his own signature, being the author of two important treatises in the "Twentieth Century Practice," one on the "Diseases of Occupation," the other on "Diseases of the Cerebrospinal and Sympathetic Nerves." We wish him personally every success in his undertaking, but we fear his chance of making money for the trustees, when Dr. Gould has so signally failed, is very small.

TO BANISH THE MOSQUITO.

The vastly increased importance to humanity, which the mosquito has assumed during the past year, renders all that pertains to this pest peculiarly interesting at the present time.

While it is not strictly new or novel, it is still noteworthy as being communicated to the State department in Washington by Consul Plumacher, of Maracaibo, that the ricinus communis or castor-oil plant is so distasteful to the insect that it will remain neither about premises where these trees are planted, nor in appartments where the cut branches, leaves, and seeds have been exposed.

Even in cold climates it is said that plants four or five feet in height can be raised from the castor seeds, and under favorable conditions will grow in great profusion. If the personal experience of Consul Plumacher in keeping his household free can be duplicated by each future experimenter, sleepful nights and freedom from malaria may still be within the grasp of all who dwell in regions where the tuneful piper loves to exercise his prerogatives.

The castor plant has already done much for man. If this boon is added, we can well afford to toast it in a large bumper of its own oil.

Arsenical Beer.—At a recent meeting of the American Chemical Society in Chicago one of the speakers charged that many brewers added to their beer an antiseptic preparation containing arsenic with a view of preventing further fermentation. In the discussion it was suggested that the national government undertake special analyses of beer and other brewed liquors in order to protect the consumer from poisoning by various adulterants and preservatives fraudulently used by the brewers.

News of the Week.

The New Jersey Training-School for Feeble-Minded Children has just received a bequest of $100,000 from the Maxham estate. The legacy will pay all the outstanding obligations of the institution and leave a cash balance of about $60,000.

An Isolating-Ward on Randall's Island.—It has been proposed by the board of health to establish a ward on Randall's Island to be used as an isolating-ward for the children suffering from diphtheria, scarlet fever, or other infectious diseases.

The Tsar's Physicians who were in attendance upon him during his recent attack of typhoid fever have been rewarded in various ways. Prof. Leo Popoff has been appointed body physician to the Tsar, Dr. Tichskonoff honorary physician to the imperial family, and upon Dr. Hirsch has been conferred the order of Alexander-Nevski.

Mortality from the Plague in India.—In the course of a speech at Calcutta on Christmas day, Lord Curzon of Kedleston, the Viceroy of India, said that since the appearance of the bubonic plague, in 1898, twenty-five thousand deaths from the disease have occurred in Mysore State.

Cure of Consumption by Splenic Vibrations.—An osteopath in a Western State announced at a recent meeting of his bone-suffering brethren that he had devised a new method of curing tuberculosis, and presumably other bacterial diseases. The method consists in shaking the spleen so as to dislodge a number of phagocytes, which seize upon the specific bacilli and devour them. What the patient does, while his spleen is being vibrated, is not stated.

The Cost of Public Baths.—A striking example of the extravagance prevailing in the conduct of our city government is furnished by the offer of a charitable organization to conduct the new public baths in Rivington Street for less than half of the sum asked for by the municipal authorities. The commissioner of charities asked for an appropriation of $52,000 to run the baths for a year; the board of estimate allowed him $35,000, and now the Association for Improving the Condition of the Poor offers to do the work for $17,500 and to furnish soap and towels, articles which the commissioner did not seem to regard as necessary accessories.

Mosquitos and Yellow Fever.—A despatch to *The Sun* from Havana states that a number of inoculation experiments have been made at Marianao, the subjects being American soldiers who voluntarily took the risks involved. Four cases are now under treatment, the patients all being soldiers who were bitten by mosquitos which had previously bitten persons suffering with yellow fever. The committee which is conducting the experiments has found that a mosquito, after having bitten a person affected by the disease, needs fifteen days before it is able to transmit it. If

it bites a non-immune in less than that time he will not develop the disease. The four cases under treatment developed the fever in about three days after being bitten. Five soldiers have been living and sleeping in infected clothes, beds, and bedclothes for twenty days and have not developed any symptoms. A dinner will be given to Dr. Finlay, the originator of the mosquito theory.

City Hospital.—At the annual meeting of the medical board of the City Hospital, the following officers were elected: *President*, Dr. Edward S. Peck; *Vice-President*, Dr. D. Hunter McAllpin, Jr.; *Secretary*, Dr. Charles L. Gibson; *Chairman of the Committee of Inspection*, Dr. Charles C. Ransom.

Rabies in Rochester.—The health authorities of Rochester, N. Y., state that an epidemic of rabies is prevailing in that city, and they characterize the situation as alarming. The reports of mad dogs in Rochester for the last two months have averaged one a day, and there are so many carcasses in the hands of the health authorities at the present time that it is impossible to make autopsies on all of them.

The Study of Insanity in New York State.—At a meeting of the New York Neurological Society held January 1, 1901, the following report was read and unanimously adopted: The committee of the New York Neurological Society, appointed at the request of the president of the New York Commission on Lunacy, to offer suggestions as to a scheme of scientific study of mental diseases in connection with the State hospitals for the insane, begs leave to report as follows: 1. It is to the interests of the State that original research work should be carried on in relation to insanity, in order that the science should be advanced, and better methods of prevention, treatment, and cure discovered. This is of direct interest to the tax-payer, upon whom falls the burden of the care of the insane. 2. There should be one central laboratory in the State, wherein the energies of the best scientific men in the various departments of medicine related to insanity should be devoted wholly and exclusively to the prosecution of original research. 3. Such a laboratory, combining the labors of well-qualified workers in general pathology, neuro-pathology, psychology, chemistry, anthropology, and other requisite branches, should be able to produce from year to year results which would be creditable to the State as a patron of science, as well as invaluable in advancing the knowledge of the methods of treatment and cure of mental disorders. 4. Each hospital for the insane should have upon its staff of medical officers one physician whose sole duty it should be to conduct ordinary autopsies and to carry on the routine duties of a clinico-pathological microscopist. 5. The central laboratory, or pathological institute, should be freely open to any qualified scientific men, for the prosecution of original research work, under the direction of the laboratory experts, preference always being given to the qualified men in the State hospitals. But systematic teaching of fundamental principles should not be required from any of the departments of the laboratory. The scientific men in charge of the various departments of the pathological institute should devote all their energies to original investigation, and not be taxed, hampered, or interfered with by medical men who are able to obtain instruction in fundamental principles elsewhere, without cost to the State. 6. The central laboratory for original research should be a part of a reception hospital for the insane, situated on Manhatten Island.

Gifts to Charitable Institutions.—The following bequests to charitable institutions in New York and vicinity were provided for in the will of the late Mr. Henry Villard: New York Infirmary for Women and Children, $10,000; the German Society of New York, $5,000; the Charity Organization Society, $2,500; the State Charities Aid Association, $2,500; the New York Society for the Prevention of Cruelty to Children, $2,500; New York Medical College and Hospital for Women, $5,000; the German Hospital and Dispensary, $10,000; Dobbs Ferry Hospital Association of Dobbs Ferry, N. Y., $5,000.

A National Leper Colony at Molokai.—The *Hawaiian Gazette* protests energetically against the proposal which has been made to establish a national leper colony on the island of Molokai to which all lepers in the United States may be sent to be taken care of by the government. *The Gazette* says it is time that the board of health, chamber of commerce, and other organizations, as well as private citizens, began to take active steps to let the people of the United States know that the Molokai leper settlement is not a national institution, but a local territorial one, maintained by local taxation, and that the residents of Hawaii resent the proposition to fasten upon Hawaii the perpetual stigma of leprosy.

A Discussion on Cinchona Barks.—At the regular meeting of the New York College of Pharmacy, 115 West Sixty-eighth Street, to be held on Tuesday evening, January 15th, the subject of "The Cinchona Barks of the New York Market" will be presented by Mr. J. H. Stallman, and discussed by Mr. Albert Plaut and others. Mr. Stallman will illustrate his remarks by an elaborate series of specimens, and the college collections of barks and herbarium specimens will be exhibited by Professor Rusby, the entire series of specimens constituting probably the most extensive cinchona collection ever brought together in this country.

The Maine State Hospital for the Insane at Augusta is now so crowded that the need of a new hospital is urgent. A site for a new hospital at Bangor was purchased eleven years ago, but the building, although completed, is not yet ready for occupancy, owing to the failure of the legislature to vote the necessary appropriation. It is hoped that the present legislature will provide a sum sufficient for the purpose and that some of the patients may be transferred from the Augusta hospital in April. The latter hospital, which was built to accommodate five hundred patients, has now over seven hundred and fifty pa-

tients. When the congestion is relieved by the opening of the Bangor hospital, the building at Augusta will be enlarged.

The Brooklyn Society for Neurology.—At the annual meeting of this society, held December 27, 1900, Dr. W. H. Haynes was elected president and Dr. B. Onuf secretary for the ensuing year.

The State Hospital for Consumptives.—The trustees of the proposed hospital have selected a second site for the institution at Raybrook, midway between Saranac Lake and Lake Placid and not far from the Lake Clear site, first chosen, which met with opposition. No action on the matter has been taken yet by the State board of health and the State forest preserve board, it being held that the price asked for the site ($10,000 for about five hundred acres) is too high. It is believed that the proposed Dannemora site has been definitely abandoned.

The Anti-Vaccinationists have been strangely silent during the present vaccination boom, but they have been aroused at last and have held a meeting in Brooklyn. The chief speaker advocated violent measures against the corps of vaccinators and boasted that he had treated thirty cases of smallpox (successfully, of course) which he had not reported to the health authorities. This example of law-breaking pleased the audience immensely, and the society immediately voted to consider "what steps can be taken to arrest the groundless smallpox scare raised by the board of health, and to arrest and punish the lawless and tyrannical conduct of said board in breaking into the houses of citizens and forcibly injecting into their blood the putrefying matter of a sore."

The Castor-oil Plant and Mosquitos.—The United States consul at Maracaibo, Mr. Plumacher, writes to the State department as follows concerning a remedy against mosquitos, which, he says, "consists in planting the castor-oil plant (*Ricinus communis*, or *Palma christi*) around the house and premises. In cold and temperate climates the castor-oil plant grows to a height of four or five feet; in these countries it becomes a tall tree and is perennial. It seems that the smell of the plant is disagreeable to mosquitos and other insects, and it is an acknowledged fact that where these plants grow few mosquitos are found. My personal experience bears this out."

The Army Veterinary Corps.—The Secretary of War has sent a protest to the committee on military affairs of the Senate against the amendment to the army bill creating a corps of veterinary surgeons. The secretary says he is not opposed to suitable recognition of veterinarians; and he has no serious objection to giving them military rank, although he does not think it is a wise course to give military rank to civilian employees. But he does object very strongly to the creation of a new corps with a colonel at the head reporting directly to the Secretary of War, and thus necessarily creating a new bureau in the war department and a body of officers who, communicating directly with the Secretary of War through their chief, are necessarily independent of the commanding officers of the cavalry regiments and the horse artillery organizations.

"The New York State Journal of Medicine" is the first of the new journals of the century to reach our table. It is to be published monthly by the New York State Medical Association and will take the place of the annual volume of transactions of that society. The first number presents a neat appearance. The original articles are on "The Successful Treatment of Ichthyosis Hystrix by the Electric Arc Light," by G. W. Goler; "The Relation of Migraine to Epilepsy," by Alvin A. Hubbell; and "Trichinosis," by H. C. Gardinier. It contains also the transactions of the latest meeting of the New York State Medical Association, together with the charter and the by-laws of the society.

Charter Revision.—Among the changes recommended by the commission appointed to revise the charter of Greater New York are some of medical interest. Among these the most important is that affecting the board of health. The commission recommends that the board be composed of one commissioner, to be selected by the mayor without restriction upon his choice, and of the police commissioner and the health officer of the port. The powers and duties of the health department are not materially changed. The commission also declares itself of the opinion that there should be no discrimination against medical men in this appointment, and that the absurd and insulting provision which prohibits the appointment of a physician as president of the board of health be rescinded. Another interesting change is one recommended in the matter of the board of public charities. It is that Bellevue and its subsidiary hospitals, viz., Fordham, Harlem, Gouverneur, and the Emergency Hospital, be placed under the administration of a board of seven trustees, the board to be so appointed that the term of office of one member of the board will expire each year. These trustees are to be appointed by the mayor, but to aid him in making his selection of trustees the amendment further provides that ten days previous to the date of appointment he shall call upon the presidents or other executive heads of the New York Association for Improving the Condition of the Poor, the Society of St. Vincent de Paul in New York, and the United Hebrew Charities of the City of New York to present a list of names not less than twice the number of trustees to be appointed. The mayor may, if he wishes, call upon other organizations or upon individuals to suggest names, or other organizations or individuals may suggest names if they see fit so to do, but the mayor is not obliged to appoint any of the persons recommended either by the societies named or by other organizations or individuals. This will bring Bellevue Hospital under the same system of management as that of private hospitals. This system of trustee management of city hospitals is already in force in Boston and Cincinnati. In the former city the trustees are appointed by the mayor, subject to the approval of the city council. In

Cincinnati one member is appointed by the governor, two are named by the superior court of Hamilton County, and two by the court of common pleas of Hamilton County. In both cases the appointments are made without regard to political considerations. If the plan is found by experience to work satisfactorily in the case of Bellevue, it will probably be extended so that all the city hospitals will eventually be managed under the trustee system, wholly independent of politics.

The Child Victims of Christian Scientists must be vaccinated or stay away from school, according to a recent decision of the supreme court of South Dakota. A certain man of high lineage in the sect refused to have his children vaccinated and insisted on sending them to school. The school board sent the poor things home again, and the father appealed to the courts. Here he was adjudged to have no case and now he is suffering from a thought that the will of a "scientist" is not yet the law of the land.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy for the week ending January 5, 1901. December 28th.—Surgeon R. P. Crandall detached from the U.S.T.S. *Constellation*, upon reporting of relief, and to recruiting duty at Milwaukee, Wis., and then home to wait orders. Surgeon W. A. McClurg detached from the *Indiana* and ordered to the naval training-station, Newport, R. I. Assistant Surgeon J. M. Brister ordered to the *Independence*, January 13, 1901.

Volunteer Surgeons in the Spanish War.—Dr. Nelson M. Black, of 128 Wisconsin Street, Milwaukee, requests that all men who served in the late war as surgeons of State volunteer regiments communicate with him in regard to a bill which Congress will be asked to pass for their relief. These gentlemen were commissioned captains by authority of the act of April, 1898, calling into service volunteer armies. They were paid as first lieutenants in accordance with a decision of the comptroller of the currency. Notwithstanding this, Dr. Black says they are entitled to the pay of the rank, that of captain mounted, as is evidenced by the wording of the law of Congress and the opinion of the surgeon-general and adjutant-general in respect to the law which was passed giving the captains and assistant surgeons of the volunteers raised under the act of March 2, 1899, the pay of their rank.

College of Physicians of Philadelphia.—At a stated meeting held January 2d, Dr. John H. Gibbon read a paper entitled "A Report of a Case of Cholelithiasis with the Formation and Rupture of an Abscess of the Abdominal Wall." The condition simulated and was mistaken for appendicitis until operation disclosed its true nature and permitted the removal from the gall bladder of fifty-two light-colored gall stones of uniform size rather larger than peas. Dr. Frederick A. Packard and Dr. Robert G. Le Conte read a paper entitled "The Ascites of Cirrhosis of the Liver and its Surgical Treatment; with a Report of Two Cases." The operation consisted in irritation of the peritoneum for the purpose of establishing adhesions with the liver and the development of a collateral circulation. Both cases terminated fatally, and in one, in which post-mortem examination was made, it appeared that a collateral circulation had been established and there had been no recurrence of the effusion, although previously repeated tapping had been necessary. The election for officers resulted in the selection of the following: *President*, Dr. W. W. Keen; *Vice-President*, Dr. Horatio C. Wood; *Secretary*, Dr. Thomas R. Neilson; *Treasurer*, Dr. Richard H. Harte; *Honorary Librarian*, Dr. Frederick P. Henry.

The New Pharmacy Law.—With the new year the first general pharmacy law in New York State went into effect. Extraordinary powers are conferred by it on the State board of pharmacy, composed of the following members: Clarence O. Bigelow, George C. Diekman, and Sidney Faber, of New York; Dr. William Muir and Dr. Albert H. Brundage, of Brooklyn; Warren L. Brada, of Albany; Willis G. Gregory, George Reimann, and Robert K. Smither, of Buffalo; Byron M. Hyde, of Rochester; George H. Merritt, of Newburg; Charles B. Sears, of Auburn; J. C. Smith, of Plattsburg; Edgar M. Jewell, of Batavia, and Alfred M. Palmer, of Olean. Authority is given to the board to investigate all complaints as to the quality and strength of drugs and medicines and to prevent the sale of those that do not conform to the required standard. It has also the power to regulate the working-hours of drug clerks, which in cities with a population of one million or more must not exceed one hundred and thirty-six hours in two consecutive weeks. The board may also employ inspectors to inspect all pharmacies. The new law has a stringent provision requiring that a licensed pharmacist or druggist must have supervision of every shop where drugs, medicines, and poisons are sold. There must also be an annual registration of all drug stores, for which a fee of $2 will be exacted. Licenses may also be revoked for cause. The board is further required to examine all applicants for licenses or registration, and to issue two grades of licenses, to be known, respectively, as "Licensed Druggist" and "Licensed Pharmacist," and a certificate of "Registered Apprentice," except that in cities having a population of one million or more, a license for the grade of "Licensed Druggist" shall not be issued. It also has the right to investigate all alleged violations of the new law or any other law of the State regulating the dispensing or sale of drugs, medicines, or poisons, or the practice of pharmacy, and in its discretion to bring the matter before the proper prosecuting authorities or to bring action to recover penalties in such cases as may be proved.

Death of a Famous Army Nurse.—Mrs. Anna Morris Holstein, well known to Grand Army men all over the country for her devotion to the cause of the wounded during the Civil War, died suddenly on December 31st, at Red Hill, near Bridgeport, Pa., at the age of seventy-six years. From 1862 until the close

of the war, Mrs. Holstein was engaged in the hospital service, and after the battle of Gettysburg she was matron-in-chief of a hospital in which three thousand seriously wounded men were cared for. It was largely through her influence that Washington's headquarters at Valley Forge were purchased, restored, and made accessible to the people. Her husband was a soldier in the Civil War, and after serving the period of his enlistment, was her companion and aid in hospital work.

Dr. Charles S. Turnbull, of Philadelphia, has been appointed surgeon of the First Regiment, N. G. P., with the rank of major. He has been connected with the regiment since 1862, when he enlisted as a private.

The New York Ophthalmic and Aural Institute.—The buildings on East Twelfth Street, occupied by the New York Ophthalmic and Aural Institute, have been given to the institution by Dr. Hermann Knapp, for many years executive surgeon of the hospital and dispensary.

Vital Statistics of Philadelphia.—There were registered during the year 1900 with the Philadelphia bureau of health a total of 25,078 deaths from all causes, a ratio of 19.58 to 1,000 estimated population, as compared with a total of 23,796 for 1899, a ratio of 18.78. There were 29,105 births, an increase of 664 over the previous year. The marriages numbered 9,810, an increase of 630. The number of deaths from typhoid fever was 449, as compared with 849 in 1899; from pulmonary tuberculosis, 2,717, as compared with 2,818; from pneumonia, 2,959, as compared with 2,424; from influenza, 264, as compared with 290. There were 382 deaths from measles, 898 from diphtheria as against 849, and 669 from old age as against 776.

The Late Dr. J. Henry Fruitnight.—The following resolutions were adopted at the annual meeting of the Northwestern Medical and Surgical Society:

Whereas, It has pleased divine Providence to sever by death the membership of Dr. J. Henry Fruitnight in the Northwestern Medical and Surgical Society, a membership lasting nearly a quarter of a century; and,

Whereas, We, the members of this society, desire to place on record our appreciation of the noble and self-sacrificing character of our late colleague, sadly cut down in the prime of life; therefore, be it

Resolved, That in the death of Dr. Fruitnight this society has lost a modest and congenial companion, a true friend, and a valued professional colleague, whose earnestness of purpose and unselfishness of motive peculiarly fitted him for a large and useful medical career; that he is a severe loss to this society, in which he took a warm personal interest, to the many other medical bodies of which he was a member, and also to the medical profession and the entire community; that his published writings, concise discussions, and discriminating thought are worthy of our highest regard;

Resolved, That we sincerely extend our heartfelt sympathy to the members of his bereaved family, wishing for them that consolation which the memory of such a noble life alone can give;

Resolved, That a copy of these resolutions be spread upon the minutes of this society; that duplicates be sent to the MEDICAL RECORD, *New York Medical Journal*, *The Medical News*, *Archives of Pediatrics*, and *Pediatrics*; and that an engrossed copy be prepared for the family of the deceased.

For the Northwestern Medical and Surgical Society, A. M. JACOBUS, EDWARD S. PECK, A. E. BIESER, *Committee.*

Obituary Notes.—DR. ROBERT J. LINDERMAN, formerly State senator from Bucks County, died at Philadelphia on January 6th, at the age of sixty-five years. He was graduated from the Pennsylvania Medical College in 1858, and entered upon the practice of his profession at Quakertown. He was elected to the State senate by a large majority in 1868.

DR. WILLIAM WOOD LESLEY died at Philadelphia on January 5th, at the age of seventy-three years. He was graduated from the medical department of the University of Pennsylvania in 1851, and became surgeon to the steamship *Ohio*, retiring in 1890.

Progress of Medical Science.

Boston Medical and Surgical Journal, Jan. 3, 1901.

The Differential Diagnosis of Intestinal Obstruction.—Z. Boylston Adams says that the differential diagnosis is between obstruction and dysentery, chronic aud tuberculous peritonitis, and catarrhal enteritis. From the point of view of treatment the most important differential diagnosis lies between strangulation and impaction or closure of the intestines, occluding the lumen, whether from within or from without. When palpation under ether fails to disclose the nature of the tumor, the anamnesis is of importance. The family tendency, the fact of injury or of surgical operations, of previous attacks of similar nature, of hernias, reduced or not, of the ingestion of indigestible substances, poisons, etc., should be inquired into. Examination per rectum should never be omitted, and the persistent use of high injections may often accomplish much. The employment of purgatives or opium is misleading and dangerous. When a diagnosis of intestinal obstruction is made, the surgeon should be called in.

Clinical Notes and Comments: Degenerative Disease of the Spinal Cord Associated with Anæmia.—Robert T. Edes describes a number of cases which illustrate the connection between certain fairly definite spinal symptoms not usually recognized as belonging to the well-marked system diseases, and conditions of malnutrition of the blood. It is probable that a toxæmia is a common cause of both conditions; this toxæmia is, of course, largely hypothetical, but its existence is rendered very probable by the sequence of the condition spoken of, upon quite a number of infections diseases. These are, according to Dana, influenza, acute infections diseases, diarrhœa and dysentery, possibly shock, lead poisoning and malaria. Syphilis is not mentioned by Dana, but other authorities refer to it. It is suggested that possibly some of the obscure paralyses of children who recover, as most adults do not, are in reality cases of this kind.

A Physiological Solvent in the Treatment of Pus Gases.—By Carl E. Munger.

Experiment and Experience with the Rifle.—By Henry G. Beyer.

New York Medical Jour., Dec. 29, 1900, and Jan. 5, 1901.

The Importance of Knowledge of Ear Disease to the General Practitioner.—W. H. Thomson comments upon the great difference of opinion as to the significance of otorrhœa at the present time as contrasted with thirty years ago. He suggests that we should be suspicious of any patient with an old ear lesion, who complains of headaches,

has hysterical symptoms so called, depression of spirits, etc., and should carefully note the pulse and temperature and be on the sharp lookout for brain trouble. Prognosis in a case of purulent trouble in the ear depends somewhat on the particular bacterium present. It is better with the pneumococcus than with the streptococcus. Intracranial organized exudates due to chronic ear disease often lead to persistent muscular twitching, especially just as the patient is dropping off to sleep. They indicate a cortical irritation which is often the precursor of true epilepsy. Cases of otorrhœa exciting mastoiditis are frequently difficult to diagnose. Vertigo is a most important symptom. Thomson divides vertigo into the following classes: Gastric or digestive, cardiovascular, ocular, and aural. The latter causes the most positive disturbance of all. The general practitioner should never omit to inquire into the condition of the ears, and if he suspects ear trouble and finds that he is making no headway with the case he can never be morally justified if he fails to ask an otologist to help him.

Observations on Lateral Curvature of the Spine; Pathological, Clinical, Mechanical.—By A. M. Phelps. The paper is illustrated with five pictures bringing out the points made. The author says that he never saw a lateral curve and rotation due to destruction of bone from pressure with corresponding deformity of rib removed from the spinal column by any method. The most we can do with our present resources is to prevent increase of curve, to remedy the physiological curve, and to give the patient, if possible, strength. No machines or gymnastics have any effect upon the curves and rotations *per se*. The only good they can do is to assist in holding up the spine, but so long as the ribs are bound together by contracted intercostal muscles that force can be of but little avail. Operation may straighten the curve to some extent; and after that has been done proper support should certainly be applied. The author prefers the aluminum corset, which combines the advantages of lightness, durability, thinness, and non-interference with the form or clothing, coolness from its perforations, and the fact that it can be worn during bathing.

The Importance of Postoperative Treatment after Removing Spurs of the Nasal Septum.—E. F. Snydacker insists on the necessity of careful after-treatment in cases of septal operation for granulation-tissue forms, and unless this is kept under control it will increase in size and finally come to cause as much obstruction as the original spur. Such after-care should extend over a period of two months. He declares that no operator should ever undertake to remove a spur from the septum without first explaining to the patient the necessity for after-treatment. If a patient cannot or will not submit to such after-treatment, then the operation should not be undertaken; for it is a matter of almost absolute certainty that eventually the operation will not be a success, rather the contrary, and that in the course of time the patient will be worse off than before the operation.

Hyperidrosis of the Axilla; its Treatment with the Thermo-Cautery.—L. Kolipinski thus describes the procedure followed by him. The axillary base is washed and shaved. The thermo-cautery at a bright red heat is applied, with its flat side, from ten to twenty times to the space from which the sweat is seen to ooze, namely, the area covered by hair in the adult; the triangular groove below, when the arm is elevated, for about two inches; the posterior border of the armpit, especially at its middle, and the upper external border near the hairy centre. One-half or more of the superficies is turned into burns of the second and third degrees. The cauterizing is done in a very few minutes and the pain as indicated is not severe. A dry bismuth or zinc-oxide dressing is applied, and the patient may resume his ordinary occupation in a few days.

The Ear as a Factor in Causing Systemic Disturbance.—J. L. Minor narrates the histories of several cases illustrating the point suggested in the title of his paper. The latter is a plea for systematic examination of the ears in all cases of fever without apparent cause. A purulent inflammation will frequently be found or retention of inflammatory exudates which are the cause of the general disturbance.

Some Observations upon Specialism in the Arts and the Sciences Generally, and upon Specialties and Specialists in the Science and Art of Medicine Particularly.—By William Bodenhamer.

Medical News, January 5, 1901.

Pneumonia; its Etiology and Treatment.—D. L. Burnett states that the consensus of opinion is that lobar pneumonia is caused by a germ, really by two germs, viz., the pneumococcus of Friedlander and the diplococcus of Fraenkel. They are accompanied by pus germs, and toxins are rapidly developed. Bronchopneumonia may be of a specific nature, as, for example, tuberculous or syphilitic. It is often a terminal affection. As to the treatment, an initial dose of a mild cathartic is indicated in most cases. Opium for several days will dull the nervous shock incident to the disease. Cold spongings will generally control the fever, though small doses of the coal-tar preparations may be added. The heart requires the most careful watching. A good combination is nitroglycerin, strychnine sulphate, spirits of camphor, aromatic spirits of ammonia, and spirits vini gallici, to which an opiate may be added. Alcoholics may be taken in milk, tea, or coffee. The patient should not be allowed even to rise on his elbow. Expectorants are, as a rule, not to be advised. Water or liquids will render the inflammatory products less gelatinous. Cardiac and respiratory stimulants and tonics are preferable to syrupy cough mixtures. Opium and camphor or inhalations of steam and turpentine are good for an irritating cough. Insomnia should be treated according to its cause. Delirium must be controlled. Hot spongings and rubbings, as in insomnia, are of use. A cotton jacket is often used to keep the chest at an equable temperature. As to nourishment, almost any easily digestible food is allowable. During convalescence, tonics are indicated. Iodides are of use in delayed resolution. Cod-liver oil is of much value at this time.

On the Prognosis of Hysteria: a Contribution to the Question of Fatal Hysteria.—Joseph Fraenkel reports that during a period of two years he saw three undeniable clinical pictures of hysteria end fatally. Hysteria may be divided into three principal groups: (1) Predominantly mental forms, hysterical psychoses. (2) Cerebrospinal forms. (3) Splanchnic forms. The prognosis of the first two forms is more favorable than that of the third group. In hysteria, death is due to: (1) Spasm or paralysis of any part of the respiratory mechanism. (2) Inanition resulting from prolonged hysterical anorexia or uncontrollable vomiting. (3) Paralysis of the circulatory or alimentary apparatus. It seems reasonable to state that in hysteria death, when it occurs, is due to irritation or paralysis of splanchnic or vegetative functions.

Journal of the American Medical Ass'n, Jan. 5, 1901.

The Douche in the Treatment of Ophthalmia Neonatorum.—E. E. Holt reports the case of a baby between two and three weeks old, from whose eyes came a profuse purulent discharge. There were so much chemosis and swelling of the lids that it was difficult to make a satisfactory inspection of the cornea of either eye. It was finally determined that the cornea was involved and about to break down in each eye. With a Davidson syringe, using the No. 1 point, about a one-per-cent. solution of tepid boric acid was injected into the eye—about one quart to each eye. This was repeated every half-hour, night and day, for the first twenty-four hours, then less often, till at the end of the fifth day the baby was opening its eyes and looking about the room. In using the syringe the point was always directed away from the eyeball and gradually worked along the whole length of the retrotarsal fold so that the conjunctival sac was thoroughly washed out. A two-per-cent. solution of silver nitrate was used from the first and the eyes were cleansed by irrigations, pipettes, and absorbent cotton. Care was taken that the silver nitrate did not reach the cornea; cold packs were applied to the lids between the intervals of douching, and the nourishment of the child was given all the attention possible. Recovery was complete.

Amblyopia following the Intoxicating Use of Jamaica Ginger.—Edward Stieren finds eight recorded cases, in American ophthalmic literature, of blindness following the ingestion of ginger. His own case was that of a man aged thirty-six years, who had been drinking heavily. On sobering up in a place where he could not obtain liquor, he bought

a dozen ounce bottles of Jamaica ginger, all of which he consumed in one morning. About noon he fell into a stupor from which he awoke about 3 P.M. totally blind. No other symptoms presented themselves except a consuming thirst. Vision was almost nil. The cornea was almost totally insensitive to touch with camel-hair pencil. Treatment consisted in immediate confinement to bed in a darkened room. Three hot foot-baths were given during the night, and gr. xx. each of calomel and compound jalap powder in divided doses. He received $\frac{1}{8}$ gr. pilocarpine muriate hypodermically twice during the night. Pilocarpine and calomel were continued for the next two days, when the pilocarpine was discontinued and gr. xx. doses of potassium iodide supplanted the calomel. On the fifth day the patient's vision in each eye was $\frac{20}{30}$. The lesion in these cases is believed to be an acute retrobulbar neuritis of a toxic nature.

Walled Off.—Under this title John B. Deaver studies appendicitis, concluding that: (1) Pus is an avoidable complication in the treatment of appendicitis. (2) The patient's welfare is best served by avoiding any of the complications incident to pus formation. (3) The walled-off abscess is not the blessing to be sought, but rather an evil to be avoided by prompt surgical interference as soon as the symptoms of appendicitis manifest themselves. (4) Operation on cases of walled-off pus imperils the patient's chances for recovery, on account of liability to infection of the peritoneal cavity. (5) Fecal fistula as a result of a walled-off appendicular abscess is an avoidable sequel to appendicitis and should not be permitted to occur. (6) The latter statement is true of all complications and sequelæ of appendicitis due to pus formation.

Some Cases of Tetany in Infancy.—John Lovett Morse in reviewing seven cases of this nature states that in them there was no common etiological factor. Digestive disturbances occurred in all but one. In one case they seemed the only factor; in two others, the only important factor; in two more, their influence could not be excluded. In one they were apparently not important. Traces of rickets were found in four. In no case was there craniotabes. Rickets probably acts only indirectly. Influenza and diarrhœa are possible etiological factors. Difficult dentition may favor the development of tetany. Syphilis seems sometimes to be the cause. In every case but one of these reported, conditions evidently capable of causing toxic products were present. In the one case it was also impossible to exclude some such condition. Absorption of these toxic products into the circulation, with the resulting action on the nervous system, seems to offer the most reasonable explanation of the cause of the disease. These toxic products may be of various sorts. Treatment must be directed to the cure of the primary disease, to the prevention of the formation of toxic products, and to their elimination if already formed. Symptomatic treatment is also important.

Pulmonary Tuberculosis in Early Childhood with Special Reference to its Prevention and to its Diagnosis from Other Wasting Disorders.—Arthur Latham states that the characters of pulmonary tuberculosis in very early childhood are radically different from those which obtain after the age of six years. Until the child is three and a half years of age tuberculosis is mainly dependent upon the infection of the bronchial glands and spreads from these glands to the lungs, rather than from the lungs to the glands as is the case in the adult. After the age of four years the lesions found are more comparable with the types we are familiar with in adult life. The varieties which are found up to the fourth year may be classified as follows: (1) Tuberculosis of the bronchial glands. This, of course, should not, strictly speaking, be included under the heading of pulmonary tuberculosis, but it is convenient to do so. (2) Miliary tuberculosis of the lungs. This may be dependent upon (*a*) a rapid primary infection without any discoverable old focus; (*b*) the rupture of a tuberculous bronchial gland into a blood-vessel with rapid dissemination throughout both lungs, more especially of the lower lobes; and (*c*) pulmonary infection secondary to other and older lesions, such as tuberculous disease of the testis, bone, etc. (3) Tuberculous bronchopneumonia. This may be dependent on (*a*) the tubercle bacilli obtaining a hold upon a simple persistent bronchopneumonia; and (*b*) direct spread by the lymphatics of the bronchi from a previously diseased bronchial gland. This third variety may go on, especially in the confluent form of bronchopneumonia, to what Goodhart has aptly called cheesy consolidation, or it may in rare cases go on to a fibroid condition of the lung. In children who have reached the age of six years we may have in addition to any of these varieties: (4) Pulmonary tuberculosis which approaches the adult type but differs somewhat in its distribution and in the fact that there is a diminished tendency toward the formation of fibrous tissue. He discusses the differential diagnosis of the foregoing clinical varieties and lays down general rules for treatment, which are in the main those applicable to cases of the disease in adults.

A Case of Chronic Dilatation of the Stomach Ending in Death from General Tetanic Convulsions.—D. D'Esterre's patient was a man aged thirty years, who for three years past had suffered from symptoms of dyspepsia occasionally accompanied with vomiting. At one time he was a heavy drinker and a large eater, but he became very careful and abstemious in the matter of food and drink, which even in small quantities caused him pain and uneasiness. There was no palpable tumor within the abdomen. His most troublesome complaint was the vomiting of enormous quantities of coffee-colored fluid about twice a week, sometimes nearly a gallon. He also suffered much from eructation of gas. The physical signs of gastrectasia were present. He was instructed in the use of the stomach-tube, in which he became quite expert, and often expressed himself as feeling much better after its use. However, after a slight improvement he was suddenly attacked with extremely painful convulsions of a tetanic character affecting chiefly the flexor muscles of the arms and hands and in a lesser degree those of the abdomen, legs, head, and neck. Opisthotonos was at one time marked, and he also showed the risus sardonicus. This attack was overcome with large doses of chloral hydrate, bromide of potassium, and tincture of opium, and subsequently he was given sulphate of sodium and magnesium as well as enemata to counteract the constipation. He improved sufficiently to go about again and resume his work, but he succumbed to a similar seizure a few months later.

The Pyrexia of Syphilis.—By P. W. Bassett-Smith. A man aged twenty-five years returned from the West Indies with fever of irregular type and marked anæmia. The condition of the blood and glands led to a diagnosis of pernicious lymphatic leukæmia. His temperature was remarkable, varying as much as 7° F. at times between night and morning, but without rigors and with scarcely any constitutional symptoms. The patient was treated with arsenic, iron, digitalis, etc., for ten weeks, and for a short time with mercury with chalk. Regular examinations of the blood showed the same characters throughout with an extraordinary abundance of blood-plates. As there was an old history of syphilis he was later put on iodide of potassium and bark, with the result that in three days the temperature fell to normal and never again rose.

Observations on Compressed-Air Illness.—F. R. Wainwright gives the clinical histories of nine cases, discussing the condition under the headings of ventilation, pathological effects, diagnosis, etiology, pathological theories, morbid anatomy, remote effects, and treatment. The cases came under observation during recent tunnelling for one of the underground railways in London. He believes that the cause of the symptoms is supersaturation of the blood with air. He believes that this theory explains why rapid recompression followed by a long "locking-out" is in a large majority of the cases curative of all forms of the illness, the air being re-absorbed and the "locking-out" enabling it to escape through the lungs. It also accounts for the fact that the sooner recompression is practised after the onset of the symptoms, the more satisfactory are its results.

Treatment of Purulent Pleurisy.—G. Marion emphasizes the following points in the treatment of purulent pleurisy: (1) Evacuation as soon as the presence of pus is determined. (2) Avoidance of general anæsthesia, which favors syncope and asphyxia which are comparatively frequent during operation for empyema. (3) The point of evacuation should be at the most dependent spot. (4) The pleura should not be irrigated. The writer gives an account of thirteen cases of purulent pleurisy, not tuberculous, which he has treated. Two patients died during the operation; one from syncope, the other from asphyxia. Probably if they had not been anæsthetized the accident would not have occurred. Another died a month after operation from amyloid degeneration of the viscera. His operation had been performed at least two and a half months after the beginning of the pleurisy. Another, who was not operated on till two and a half months after the beginning of the pleurisy, developed a sinus which demanded a second operation. This would undoubtedly have been avoided had the first treatment been early. The other ten patients made a rapid and complete recovery. The bacteriological examination which was made in eight cases demonstrated the pneumococcus in two cases; in one case the staphylococcus associated secondarily with the pneumococcus; in five cases the streptococcus associated with anaerobes.—*La Presse Médicale*, November 24, 1900.

The Hygienic Treatment of Tuberculosis among the Ancients.—Meunier reviews in an interesting way the ancient treatment of tuberculosis. Hippocrates believed in regular exercise and complete rest. Everything depended upon the personal equation. If exereise agreed with the patient, then that was what he should take. Hippocrates believed in the use of red wine, but substituted white in fever. The patient was advised to avoid hot viands and drinks. Celsus advised for the more robust invalids long sea voyages. For those more feeble he approved of shorter sea trips. Pliny attached great importance to the curative power of the sun. Galen made a point of high altitudes. He believed mountain air dried up the tuberculous ulcerations. The Arabs evidently realized both the contagiousness of tuberculosis and its relatively frequent cure. The school of Salerno believed in the advantages of salt and of honey, and of the milk of goats and asses. Rondelet, contemporary of Rabelais, seems to have been the first to mention the juice of meat. John Jonston regarded tuberculosis as curable even in its advanced stages. Van Swieten foresaw the rôle of respiratory gymnastics. Rozière advocated pure air, moderately dry, and especially an air whose qualities were different from that of the place where the patient contracted his disease. Raulin attached great value to the vapors of sugar. The history of this treatment reveals many curious ideas, and many points which are even at present worthy of careful consideration.—*Le Bulletin Médical*, December 1, 1900.

Excretion of Urine in Neurasthenics.—Maurice de Fleury gives among others the following results of his study of this subject: The quantity of urine excreted in twenty-four hours has been normal in twenty per cent., increased in fourteen per cent., and diminished in sixty-six per cent. The density was increased in 59 cases, diminished in 11, normal in 30. The acidity was normal 29 times, decreased 12 times, increased 59 times. Uric acid was in excess 61 times, normal 14 times, decreased 25 times. Urea was increased 35 times, decreased 57 times, normal 8 times. The phosphates were in excess 26 times, decreased 43 times, normal 31 times. It is known that in the normal individual the proportion of alkaline phosphates, *i.e.*, the phosphates of sodium and potassium, is to the earthy phosphates (phosphates of lime and magnesium) as 3 to 1. In the patients observed by the writer, the opposite conditions have prevailed. In only 19 cases out of 100 was the proportion normal. Indican or skatol was found 73 times out of 100. Only 6 or 7 times were the conjugate sulphates found. The chlorides were increased 56 times, normal 18 times, decreased 26 times. Twelve cases showed bile pigments and 10 urobilin. In 28 cases there were traces of albumin. The coefficient of oxidation was normal 18 times, exaggerated 27 times, decreased 55 times. The coefficient of demineralization was normal 19 times, increased 21 times, diminished 60 times.—*Bulletin Général de Thérapeutique*, November 23, 1900.

Tubercles in the Optic Thalamus and in the Cerebellum.—Louis Spillmann and L. Nilus report a case of this nature. The patient was a seamstress aged seventeen years. The principal symptoms were intense headache, absolute blindness, vomiting, Jacksonian epilepsy, with a pulse regular and rather rapid. Disturbances of memory or of the association of ideas were never noticed, neither were there any anomalies of sensation or motion. Intelligence was not dulled till the very last days of life: coma supervened without convulsive phenomena. At autopsy about a dozen small tubercles the size of a pea were found. They were seen in the middle of the right hippocampus. The optic thalamus on the left side was invested by a tubercle the size of an almond. The cerebellum was filled with tubercles, there being three in the right side and four in the left. Tubercles situated in the gray matter of the brain, in the optic thalamus, and in the white matter of the cerebellum of this patient did not give rise to any characteristic symptom: the symptoms observed were those commonly encountered in many cerebral affections. On this account there was difficulty in determining the exact seat of the tumor during life.—*Gazette Hebdomadaire*, December 16, 1900.

Localizations of the Bacillus of Leprosy in the Different Organs.—E. Jeanselme in his interesting paper on this subject gives the following results of blood examination. In one patient, whose blood was examined eight times in eleven days, during the febrile stage, the red corpuscles varied from 3,880,000 to 4,120,000. Hæmoglobin varied from 9.75 to 10.25. White corpuscles varied from 11,600 to 6,000. A feeble patient, an adult, gave the following count: red corpuscles, 3,240,000; hæmoglobin, 10.25; white corpuscles, 6,000. A young girl aged fourteen years, who had been afflicted with this disease since the age of eight, presented: red corpuscles, 4,400,000; white corpuscles, 4,200. An adult man (four examinations): red corpuscles, 4,760,000 to 4,880,000; hæmoglobin, 9.50 to 10; white corpuscles, 4,800 to 10,400. Adult woman (one examination): red corpuscles, 3,720,000; hæmoglobin, 9.25; white corpuscles, 4,000.—*La Presse Médicale*, December 15, 1900.

Intestinal Ulcerations in Patients Suffering from Arteriosclerosis.—M. F. Mouisset concludes from his observations that: (1) Intestinal ulcerations predominating in the large intestine are found in patients suffering from arteriosclerosis. (2) A more complete and careful examination of the intestine at autopsy will show perhaps that these lesions are more frequent than has heretofore been supposed. (3) Alterations in the intestinal vessels are the necessary condition, and are sufficient to cause the production of ulcerations especially in patients who have an increased blood-pressure. (4) Histological examination of the ulcers reveals arteritis and sclerosis of the intestinal wall. The two lesions may be concomitant, or indeed, one may be the result of the other, and in that case it can be said that the ulcerations result from arteriosclerosis of the intestine.—*Lyon Médical*, December 16, 1900.

Lead Poisoning among Lapidaries.—Ch. Fiessinger states that a large number of lapidaries in the Jura mountains are poisoned by lead. In the last fifteen years the number of these patients has diminished, owing to better hygiene and to the diminution in number of lead wheels employed by the workmen. Lead gout does not exist in lapidaries. The relatively sober life, moderate use of meat, perchance also the high altitude, all keep these men out of danger from this complication. All the other manifestations of lead poisoning are present—hysteria, dyspepsia of various forms, neurasthenia—this last generally following dyspeptic troubles, epilepsy, nephritis, anæmia, and paralysis. Tuberculosis is frequently seen among lapidaries; nevertheless it seems that those who have undergone a severe intoxication escape it.—*La Médecine Moderne*, November 28, 1900.

A New Case of Juvenile General Paralysis with Hereditary Syphilis.—E. Regis reports this case of a man aged twenty-three years. In 1899 he was transferred to an asylum and all his symptoms were plainly increased: Dementia was more profound; the inequality of the pupils and the abolition of their reflexes were more marked; speech was very indistinct, sometimes unintelligible; ataxia, muscular paresis, lingual as well as labial tremor, were very marked. The inheritance of syphilis in this case was proved and clearly accounted for the general paralysis. The writer also notes in this young man the occurrence of a fracture of the left femur, which was almost spontaneously caused by a misstep: the cause of the fragility of the bone was probably faulty nutrition.—*Journal de Médecine*, December 16, 1900.

Münchener medicinische Woch., Dec. 11 and 18, 1900.

Contributions to the Question of Traumatic Movable Kidney.—E. Payr cites at some length the opinions of various writers as to the protean etiology of this affection, from which it appears that a distinct bodily type predisposes to the displacement. The characteristics of this habitus are

defective or faulty development of the paravertebral niches, general poor muscular development, relaxed abdominal parietes, diastasis of the recti, non-resistance of the hernial openings, enteroptosis, abnormalities in position of the genitals, weakness of the pelvic floor, etc. Traumatism has always been held to play a doubtful rôle in the causation of the trouble, but the author fully agrees with those who assign it a prominent place. The forms of violence which are apt to have renal displacement as a sequel are (1) shock in the direction of the long axis of the trunk, such as occurs in falls on the feet or buttocks (*e.g.*, the floating kidney of equestrians), (2) blows or falls on the lumbar region, (3) forcible compression of the thorax which may produce either direct dislocation of the organ or simply a loosening of its fastenings so that the mobility is a secondary result, (4) muscular traction. The author is of the opinion that too violent or improperly performed massage is also capable of causing the trouble, and describes three cases in which the lesion was apparently the direct consequence of such manipulation. This does not, however, invalidate the benefits supposed to follow such treatment for the cure of the movable kidney itself; it simply emphasizes the necessity for careful training on the part of those to whom such manipulations are entrusted, and calls attention of practitioners to the dangers attendant on their improper performance.

Acute Iodism and its Relation to the Rhodan of the Saliva and the Nasal and Conjunctival Secretions.—O. Muck seems to have discovered a reason for the notorious susceptibility which some persons exhibit to intoxication with potassium iodide. Having accidentally, in connection with another research, made the discovery that the saliva of a patient suffering from middle-ear disease, which had supposably destroyed the chorda tympani nerve, was free from rhodan, tests on a considerable number of individuals revealed the fact that this constituent of normal saliva is present in very variable amounts, or is even entirely absent. It was found that whenever the percentage of rhodan was high, the intolerance to iodide was also great, while the cases notable for a deficiency of this substance bore the drug especially well.

Experiences with Angiotripsy.—E. Winternitz reports on a series of one hundred and fifty major abdominal operations in which angiotribes of various models were employed to check hemorrhage. The results were not quite as favorable as others that have been published, for two of the four deaths reported were directly attributable to secondary hemorrhage setting up fatal peritonitis, even though ligatures were applied to the compressed tissues after removal of the instrument. Of the various forms of angiotribe experimented with, that of Doyen was found least satisfactory, those of Thumim and Tuffier also had several disadvantages, while even the most efficient of all, viz., Zweifel's, does not insure absolute safety nor preclude the necessity for careful ligation of the stump after compression.

Chloral and Hemorrhage.—A. Model ascribes a series of very severe hemorrhages from the stomach, lungs, intestine, and nose, which he himself suffered from, to the habitual use of chloral as an hypnotic. Before the use of the drug was begun, in spite of a hæmophiliac family history, no bleedings ever occurred; after it had been taken for some time, the hemorrhages were frequent, but again were conspicuous by their absence during a period of four years of chloral abstinence. Finally, at the end of this time, moderate indulgence in the drug was followed by a recurrence of the bleeding.

The Capacity for Work of the Fatty Heart with Aortic Insufficiency.—A. Hasenfeld's conclusions are as follows. (1) Animals with aortic insufficiency feel the effects of phosphorus poisoning much more noticeably than do those with normal hearts. (2) A hypertrophied heart with aortic insufficiency shows a special tendency to fatty degeneration. (3) Moderate degrees of acute fatty degeneration do not influence the strength and capacity of the hypertrophied heart muscle either for ordinary or increased exertion. (4) Excessive degrees of acute fatty degeneration lead to a weakening of hearts with aortic insufficiency and even to a fatal result by means of the circulatory disturbances thereby induced.

Remarks on Scrofula and Tuberculosis with a Contribution on Tuberculosis of the Conjunctiva.—W. Uhthoff reports a case of tuberculosis of the conjunctiva occurring in a girl aged fifteen years, describing the gross appearances and stating the fact that the diagnosis was confirmed by results of the tuberculin test and by examination of a portion of excised conjunctiva. Evidence of slight invasion of the lungs was present. The article must be read in the original by those interested.

The Dietetic Treatment of Hyperacidity.—E. von Sohlern describes a round of dietetic experiments. The author believes that carbohydrates are not only admissible in this condition, but that they have a distinctly beneficial effect.

An Attempt to Cure Lung Hernia.—By O. Vulpius.

Diabetes Mellitus.—By C. von Noorden.

Deutsche medicinische Woch., Dec. 13 and 20, 1900.

Athyreosis in Childhood.—Quincke contributes two case histories which illustrate how much is still obscure in the knowledge of diseases of the thyroid gland. In the first the child appeared healthy at birth but soon afterward showed symptoms pointing toward some abnormality of development, and when brought under observation presented an appearance strongly suggestive of cretinism. Under protracted treatment with iodothyrin and thyraden very appreciable improvement followed, but the patient succumbed to diphtheria at the age of four years. Contrary to the rule in cretinism the child did not stop its growth in height, though at the autopsy it was found that the thyroid gland, which originally had been palpable as a very small nodule, had totally disappeared. In the second case the child seemed normal to its parents for over a year after birth, when it developed a type of myxœdema accompanied by a peculiar suppuration of the gums which caused the loss of all the teeth. At the age of two years no thyroid gland could be made out, and a systematic course of iodothyrin was begun with most gratifying results, which seem permanent, for now (three years later) the child still appears normal in every respect. The author suggests that possibly accessory thyroids or the thymus have taken up the functions of the absent thyroid.

Adenoid Changes of the Cervix during Pregnancy, Labor, and the Puerperium.—C. Hennig says that the best treatment for the adenoid vegetations of the cervix, often occurring during pregnancy and easily mistaken for erosions, consists in warm cleansing douches. These may contain boric acid, aluminum acetate, or silver nitrate; copper sulphate is not to be recommended. Excision of the diseased area is permissible, the wound being closely sutured. The trouble often remains stationary for long periods of time, causing no pain but giving rise to frequent bleeding. Cauterization with the silver stick is allowable only at long intervals, the use of acid nitrate of mercury being less liable to be followed by secondary hemorrhage. During labor lacerations are predisposed to by the soft succulent nature of the granulating tissue, and it is important to restrict the bearing-down pains and not to apply forceps till full dilatation has taken place. In the puerperium the condition affords favorable sites for infection, and antiseptic douches are indicated. Excision is never followed by recurrence.

A New Method of Obtaining the Patellar Reflex.—Walbaum describes a manœuvre intended to facilitate the technique of this reflex in difficult cases. The quadriceps is relaxed in the usual way either by having the patient cross the legs, or, preferably, seating the patient on the edge of the chair and allowing the heel to rest on the ground with the leg semi-extended. The half-closed hand is now applied to the knee in such a way that the finger tips rest on the inferior patellar ligament, and the upper border of the patella is embraced between the thumb and little finger. A slight blow with the other closed fist now both gives a shock to the ligamentum patellæ and also jerks the bone downward, the double act producing a summation of stimuli which never fails to elicit the reaction if it is present. Even if not visible to the eye, the finger tips can appreciate the slightest twitch of the tendon.

The Relation of Cholelithiasis to Disease of the Pancreas and to Fat Necrosis.—Eugene L. Opie states that the association of these two conditions has been mentioned by a number of writers. When anatomical conditions are favorable disease of the pancreas may occur as a complication of cholelithiasis when a calculus passes along the common bile duct. The lodgment of a stone near the orifice of the bile duct, where it may at the same time compress and occlude the duct of Wirsung, is not uncommonly a cause of pancreatic lesions and disseminated fat necrosis. Should a calculus become impacted in this position the cases reviewed by Opie show that one of several conditions may result: (1) An individual, usually in fairly good health, with perhaps a history of previous gall-stone colic, is suddenly attacked with pain in the epigastric region, accompanied by vomiting and followed by collapse. Death occurs usually within forty-eight hours, and at autopsy gall stones are found in the bile passages, while the one which caused the fatal attack may be still lodged in the common duct near its orifice. The pancreas is enlarged, infiltrated with blood, and hemorrhage may have occurred into the surrounding tissue. Foci of fat necrosis are usually present. (2) A fatal termination may not follow rapidly the symptoms mentioned. Pain in the epigastrium persists, jaundice may be present, and a tumor mass above the umbilicus may indicate a probable lesion of the pancreas. At the end of one or more weeks or months death occurs, often with symptoms indicating the presence of suppurative inflammation, presumably in the neighborhood of the gland. At autopsy the diagnosis of cholelithiasis is confirmed by the presence of gall stones in the gall bladder or in the bile ducts, and occasionally the offending calculus is still lodged near the junction of the common bile duct and the duct of Wirsung. The pancreas is dry, black, and necrotic, and evidence of previous hemorrhage may be present. Secondary infection has occurred and the pancreas lies in an abscess cavity formed by the bursa omentalis. In the wall, and often widely disseminated in the abdominal fat, are foci of necrosis. Since the individual has survived the primary lesion, opportunity has been given for the development of secondary changes in the injured pancreas and neighboring fat. (3) In certain instances long-continued or repeated obstruction of the pancreatic duct by gall stones does not cause the acute lesions described, but produces chronic inflammatory changes.

A Report of a Case of Typhoid Pleurisy.—According to Hermon Camp Gordinier and August Jerome Lartigau, pleurisy is not a common complication of typhoid fever. When present, it is ordinarily secondary to pneumonia, to an infarction, or to gangrene. Primary pleurisy is regarded as very rare. The more common members of the pyogenic group of micro-organisms are generally demonstrated. A very few reports show the etiological relationship of the typhoid bacillus to certain cases. One case was that of a man aged fifty-seven years. After examination of the patient, a diagnosis of probable typhoid fever was made. Later the urine was found to give a distinct diazo reaction; the blood showed a positive Widal reaction, no leucocytosis, no plasmodia. Four days later there developed a large right-sided pleural effusion. The bacillus typhosus in pure culture was isolated from the aspirated fluid. In these cases the left side is generally affected. They occur mostly in men. The third week of typhoid seems to be the favorite time of onset. In the majority of cases the exudate, although hemorrhagic and serofibrinous, is also purulent.

A Study of a Case of Gonorrhœal Ulcerative Endocarditis, with Cultivation of the Gonococcus.—August Jerome Lartigau concludes that: (1) Gonococcal urethritis may be the starting-point for a fatal septicæmia induced by a pure infection with the gonococcus. (2) Endocarditis and arthritis are occasionally complications of such an infectious disease. (3) The endocardial processes may be incited by the gonococcus without the association of other organisms.

A Plea for Naked-Eye Diagnosis and Removal of the Entire Organ with the Neighboring Area of Possible Lymphatic Infection in Cancer of the Larynx.—John N. Mackenzie speaks of the three principal methods of diagnosis in laryngeal cancer in the order of their practical usefulness and importance: (1) The naked-eye method, or diagnosis by direct inspection, supplemented by clinical phenomena; (2) thyrotomy; and, finally, (3) the microscope. The second method is often included in the first. It is impossible to exaggerate the importance of naked-eye diagnosis in the detection of laryngeal cancer. Every resource and refinement of clinical diagnosis should be resorted to before an appeal to the microscope is made. The removal of the "piece for microscopic examination" too often means only the beginning of the end. Thyrotomy is justifiable when laryngoscopic examination either leaves reasonable doubt as to its true nature, or manifestly fails to define the exact territory occupied by the disease. The partial extirpation of the tumor for purposes of microscopic diagnosis is admissible only as a measure of the very last resort. The objections to the removal of tissue for examination are: (1) It subjects the patient at once to the dangers of auto-infection at the point of incision and to metastasis elsewhere. (2) It stimulates the local growth of the cancer. (3) Finally, the method is often inconclusive, misleading, and sometimes practically impossible. Cancer is an infectious process whatever may be its cause. Serum therapy will some day play the most conspicuous rôle in the treatment of this disease. Early total extirpation of the entire larynx with its tributary lymphatics and glands, whether the latter be apparently diseased or not, is the only possible safeguard against local recurrence or metastasis. No operation for laryngeal cancer is complete without the removal of the neck lymphatics. Only when this method is followed will the statistics and prognosis of this disease become more favorable.

Heredity in Diabetes Mellitus, with a Report of Six Cases Occurring in a Family.—J. Hall Pleasants makes this report and observes certain peculiar features of the family type of the disease, as follows: (1) The occurrence of the disease in an uncle, aunt, or cousin, while the parents escape, is very often observed. This may be conveniently spoken of as the "collateral inheritance" of diabetes. In the same way a grandparent may be diabetic while the parent escapes. (2) When successive generations are affected, there is a tendency for the disease to develop at a progressively earlier age. (3) When more than two members in the same generation are diabetic, there is a tendency for the disease to appear at approximately the same period of life. (4) While hereditary diabetes developing in the first two decades is often of a severe character, the cases developing later in life are generally of a mild type. (5) In a certain number of cases the disease has appeared in the children prior to its occurrence in the parents. (6) There is frequently a neuropathic tendency in diabetic families. Cases are recorded in which several children were diabetic, while the others suffered from various psychoses. (7) Obesity is often a characteristic of families in which diabetes occurs.

Experimental Injection of Testicular Fluid to Prevent the Atrophy of the Prostate Gland in Dogs, after Removal of the Testes.—George Walker sums up the results of his work on this subject as follows: The prostate gland in the injected animals presented both macroscopically and microscopically the same changes that had occurred in the uninjected ones. It may be said, therefore, that the injections of the testicular fluid had apparently no effect whatever, and one is probably justified in concluding that the atrophy of the gland is in no way connected with the absence of any substance in the testicular secretion.

Archives of Otology, December, 1900.

Aural Complications of Scarlet Fever with Twelve Post-Mortem Observations.—By B. von Gaessler. The author arrives at the conclusion that his observations tend to show a relation of the middle-ear disease to the exanthem. Simple hyperæmia, secretory process, fibrinous exudate, form the progressive states of the ear disease due to infection. In the only case in which no material alteration was found, the length of time since the initial infection may have permitted the subsidence of the ear symptoms while the nephritic condition supervened with fatal result. The fibrinous deposit in the middle ear, in the pharynx, and on the tubes, and the purulency of the atlanto-occipital joint present the most intense state of infection. In the single instance in which the cartilaginous portion of the tube showed evidences of recent inflammatory alterations, the opinion of Moos, that the infection can spread along the tubal mucous membrane, seems tenable. The normal condition of the cartilaginous tube in all other cases lends strong probability to the view that the ear disease is a manifestation of the general infection and not an extension of the infectious process in continuo. While the relatively small

number of examinations permit the expression of only a probably invariable participation of the ear in scarlet fever, they show that pronounced inflammatory processes can exist behind a normal or nearly normal drum membrane. In scarlet fever, the condition seems analogous to measles and diphtheria, in which an invariable participation of the ear has been proven.

Shall the Antrum be Opened in Acute Empyema?—E. F. Snydacker says that the antrum may be a source of danger in acute empyemas in two ways: If the mucous membrane becomes swollen, because of the peculiar anatomy of the parts the outlets of the antrum are easily shut off and an undrained empyema of the antrum ensues; or certain pathological changes occur in the antrum, such as polypoid degeneration of the mucous membrane, formation of granulations, necrosis of the bony walls, etc., which cause the antrum itself to become a focus and disseminator of infection. In every operation for acute empyema of the mastoid cells, unless the operator makes it a routine practice to open the antrum, he must ask himself these two questions: Is the antrum drained? Has it undergone such pathological changes that it is a focus of infection? If he is in doubt on either of these two points, then he must open the antrum.

Zeitschrift für klinische Medicin, vol. xlii., Nos. 1 and 2.

The Diagnosis of Aneurism of the Aorta and Innominate Artery and their Treatment by Subcutaneous Injections of Gelatin Solution.—Josef Sorgo reports a considerable number of cases of various types of hemorrhage in which an attempt was made to produce hæmostasis by the subcutaneous administration of gelatin solution. While the results in some instances were good, the author's opinion is that as yet the fervid statements made by some of the advocates of the method are unjustified and also that we are still wholly in the dark as to how the beneficial effect when present is produced. Applying the measure more particularly to aneurisms the conclusions are somewhat similar. Massing his own cases with others reported and omitting all the doubtful ones, it appears that in thirteen out of thirty-four cases coagulation in the aneurismal sack was produced, while in twenty-one the result was negative. Of these the successes were all in the saccular form, while in the fusiform dilatations nothing but failures were noted. It is hard to determine just how much value attaches to the amelioration following such treatment, for, being accompanied by the additional factors of rest in bed and milk diet, which by themselves are sufficient to cause great subjective and objective improvement, we cannot ascribe the benefit to the injections alone. Furthermore, the facts that the element of coincidence must be dealt with, that the percentage of failures is so large, and that all experimental evidence for the coagulating power of gelatin solutions is lacking, all combine to render one chary of giving a positive opinion. The strength of solution employed was from four to five per cent., thrown under the skin of the thigh or abdomen in quantities varying from 100 to 150 c.c., and repeated every two or three days. Under strict antisepsis the injections themselves are harmless, though in renal disease it is perhaps preferable to give the solution by the mouth. Severe pain and some fever are often produced, but soon subside without treatment.

The Cause of Sickness in Rarefied Atmospheres.—E. Aron has endeavored to throw some light on the peculiar malady known as mountain sickness by conducting a series of experiments in which atmospheric air, air under a pressure of 380 mm. of mercury, and pure oxygen were inhaled and the respiratory activity recorded. His conclusion is that the change in respiration accompanying rarefaction of the inspired air rests upon two components, viz., both the physical and the chemical differences from the normal which such an atmosphere possesses. It follows that great relief will be given to the distress that prevails under such conditions if pure oxygen be inhaled, for thus the chemical element at least can be eliminated, though the physical conditions are still unchanged.

A Contribution to the Study of the Late Forms of Cyanosis of Peripheral Origin.—Thomas reports a number of cases of cyanosis occurring late in life, in which the lesion usually found in such disease, viz., patency of the foramen ovale, did not exist. Given a damaged lung and a hypertrophied right heart the abnormally large charge of blood that pours through the lungs which are already impaired in function is not sufficiently aerated and cyanosis results, and the author explains his cases on this basis.

Extra-Buccal Alimentation, Especially per Rectum.—H. J. Vetlessen cites a number of cases of ulcus ventriculi in which he had recourse to this method of feeding, but dwells more especially on a case of cancer of the œsophagus, in which he prolonged the life of the patient for seventy-one days by the use of nutritive enemata. As a rule he uses milk, to which are added the yolk of an egg, a little salt, port wine, and opium. Subcutaneous injections of olive oil are given at the same time. As the exclusive use of nutritive enemata does not supply enough liquid to the organism, copious salt-water injections or subcutaneous injections should be given.

The Treatment of Pulmonary Tuberculosis.—C. F. Larsen urges that the patient be not kept too much in bed, but have a moderate amount of exercise in order to induce deeper respirations and improved circulation of the blood.

Exanthemata due to the Internal Use of Quinine.—Kristian Grön reports five cases observed. In four of these the exanthem occurred as the usual erythema, with subsequent desquamation; in the fifth case the form was papular, together with a certain amount of urticaria. The doses of quinine causing the eruption were very small. Itching and inflammation were severe. In one case there was a slight rise of temperature. One or two of the patients complained of a feeling of tension in the neck, chest, and thighs.

OUR LONDON LETTER.

(From our Special Correspondent.)

BEER AND ARSENIC—PARASITOLOGY OF MALARIA—THORACIC ANEURISM—ALLEGED DEATH FROM X-RAYS—OBITUARY—DRS. J. M. WINN, PARSONS, AND DUNLOP.

London, December 21, 1900.

Our talk is still of beer and arsenic. This is not surprising, considering that all the materials used in brewing have been subjected to analysis and almost all furnish instances of contamination. I may give as an example that Dr. John Brown, M.O.H., of Bacup, reports he found arsenic in rubber tubing and lead pipes which were used to take the beer from the pumps to the barrels. New pipes and tubing were also found to give the reactions of arsenic. On the other hand, the expert committee appointed by the Manchester Brewers' Association has not found arsenic in brewing materials except in the glucose supplied by one company. But Mr. William Thomson reports to the Manchester and Salford Sanitary Association that he has found arsenic in a number of samples of malt, and, assuming it all went into the beer, the quantity would be as great as in the contaminated glucose beer.

Other analysts have detected the poison in beer brewed from malt and hops. Both these materials are said to have been sometimes contaminated, and it is suggested that the poison is derived from the coke fires used in the drying houses. Altogether there is a great amount of evidence accumulating to show that from one source or another the contamination is widespread.

Dr. Patrick Manson last week communicated to the Medico-Chirurgical a summary of the parasitology of malaria with special reference to prophylaxis. It was conjectured years ago that, a part of the cycle being outside the body, it was probable that some blood-sucking insect was concerned. At length Major R. Ross demonstrated that the parasite entered the mosquito stomach, and he then pursued his investigation on birds. He found the proteosoma of the sparrow passed from the stomach to the salivary gland and so to healthy birds. But MacAllum showed that the parasite, although asexual in the human host, became bisexual in the mosquito, and that the female when impregnated entered the stomach wall. But these are still questions for further research. We do not yet know what circumstances determine the development of the asexual or bisexual phases respectively; nor what becomes of the parasite during the latent period, which is sometimes very long. A further unsolved problem is, why crescents are so often found in this country; in Italy during late au-

tumn, but very rarely in the tropics or in Italy during summer and early autumn.

As to the kind of mosquitos. Hitherto only the Anopheles have been found to convey the infection, and of these five out of forty-six known species have been proved to do so. Of the culex there are some two hundred and fifty species, but of the few tested none have been found carriers of the parasite. As to blackwater fever, Dr. Manson said Koch's idea that it is caused by quinine is quite untenable. The notion that it is only intense malaria is not supported by some of the facts. There is also a lack of confirmation of other conjectures, such as a special type of parasite or one of increased virulence from having passed through a particular species of mosquito.

Dr. Sambon then read a paper by himself and Dr. G. C. Low giving an account of their residence at Ostia in the Roman Campagna from July 19th to October 19th. With two other persons they occupied a mosquito-proof hut, and all four remained unaffected by malaria and are still quite well, though all the inhabitants of the neighborhood suffered, as did also fourteen healthy policemen who were sent into the district. They found the risk of being bitteu in the daytime was so slight that they would go out freely, aud they gave up the use of veils, which they wore at first in their excursions. They conclude that mosquitos are the sole agents of transmission, and that protection from their bites can easily be obtained and will give absolute immunity.

The Medical Society has held a debate extending over two evenings on "The Diagnosis and Treatment of Thoracic Aneurism." It was opened by Dr. Haviland Hall, who read the notes of a case of aneurism of the transverse and descending aorta. Among the points suggested for discussion were the diastolic thud, tracheal tugging, Roentgen rays, Tufnell's treatment, iodide, calcium chloride, gelatin injections, tracheotomy. You will see there was plenty of room for discursive remarks and opportunity for expressing such opinions as any speaker may have formed.

Sir W. Broadbent thought diastolic shock when present diagnostic, but its absence was not good evidence. Tracheal tugging was interesting, but not diagnostic. Potassium iodide was the chief treatment. Tufnell's, to an extreme degree, was not advisable.

Dr. Maguire was of the same opinion, and asked if ever a workingman had been cured by Tufnell's plan so as to be able to resume work? He believed the good results described by Lancereaux to be real and the plan safe if due care were exercised. About three ounces of a sterilized warm solution of gelatin in decinormal salt solution could be injected into the intermuscular tissue, preferably of the buttock. He had used the method in four cases, and there was evidence of consolidation in the sac.

Dr. Oswald Browne said aneurism of the transverse part often began on the posterior surface, and as physical signs were absent pressure symptoms were of the greatest importance. He mentioned a case in which a man returned to heavy work after treatment by chloride of calcium and rest.

Dr. Kingston Fowler thought both the diastolic thud and tracheal tugging were of value. The latter he had always found associated with aneurism except in one case of mediastinal tumor. Tufnell's treatment was contraindicated in the presence of aortic regurgitation, as it would probably break down compensation. In three cases treated by Lancereaux's method he could not say it had done any good.

Dr. Gilhart Smith had seen no benefit from Tufnell's treatment nor from Lancereaux's.

Dr. S. Taylor thought tracheal tugging of little if any diagnostic value, and had seen no benefit from Tufnell's treatment.

Dr. Cantley thought the plan was often tried in unsuitable cases. He had seen improvement under it when combined with chloride of calcium in a case of abdominal aneurism.

Dr. Sanderson, of Brighton, thought neurotic patients unsuitable for Tufnell's plan.

In his reply, Dr. Hall said iodide of potassium alone was less efficient than in conjunction with low diet. He was not impressed with the gelatin plan, but felt it too early to judge, as aneurisms often lasted for years.

"That the deceased met her death from shock and exhaustion following the accident and the effects of the Roentgen rays upon a weakened system, no blame attached to either the medical man or the photographer." This was the unanimous verdict of the jury in an unfortunate case at Hastings, which has caused a good deal of excitement. There are several points in the case which deserve attention, such as the length of the exposure, distance of the tube, age and condition of the patient. Evidence was offered on these which satisfied the jury, but which a medical expert with Roentgen rays might have been inclined to question. But the point for the profession to weigh seriously is the propriety of entrusting to photographers the taking of skiagrams for medical purposes. When, as in this case, legal proceedings arise, such a course is dangerous, and even for ordinary diagnostic purposes it is most unsatisfactory.

But the profession is far too lax in this and other things. It is too common to commit to unskilled persons what should be carried out by medical men. At one time anæsthetics were often entrusted to any one, but the danger of doing so has been sufficiently accentuated.

The present case shows that only medical *x*-ray experts should be employed. It is just to them that the advantages of their labors should not be usurped by tradesmen. It is very unjust to patients to expose them to dangers which a medical man would be sure to avoid. It is indecorous, too, to introduce non-medical operators to cases of this kind.

Another way in which the profession shirks its work is in entrusting so much of it to nurses. I have always protested against allowing them to give hypodermics, aud am glad to see that Sir D. Duckworth in a recent address condemned the practice. Speaking of the abuse of anodynes, he said for much of it the "profession is to blame," and "the frequent handing over of hypodermic syringes to nurses is also to be blamed." But the very men who do such things will cry out against the encroachments of unqualified practitioners.

Dr. James Mitchell Winn died on the 8th inst. in his ninety-second year. He was perhaps best known from his contributions to *The Journal of Psychological Medicine* and as a doughty champion of Christianity. His "Collapse of Scientific Atheism" appeared in 1880; but long before that he had written on "General Paralysis of the Insane" (1847) and on "The Nature and Treatment of Hereditary Disease" (1869). Perhaps the last named was his most important work from a medical point of view. As late as 1894 he renewed with remarkable vigor his fight against atheism in a treatise on "The Fallacies of the Materialistic Theory of Physiological Psychology."

Dr. Courtenay Charles Parsons, civil surgeon in the South African field force, died on the 3d inst. of typhoid. He took his diplomas in 1896. His brother, a lieutenant, was killed at the battle of Driefontein. These two were the sons of Dr. Parsons, of Dover, former treasurer of the British Medical Association, for whom general sympathy is felt.

Dr. C. S. S. Dunlop, whose death at Lagos is reported, at the early age of twenty-seven, was the son of Dr. Dunlop, of Jersey, who has other sons in the service in Africa.

THE TREATMENT OF GASTROPTOSIS.

To the Editor of the Medical Record.

Sir: I read with deep interest Dr. Lockwood's recent valuable contribution to the subject of gastroptosis. I was surprised, equally with Dr. Rose, not to see the "plaster bandage" mentioned as at least a means which might be tried in the management of these cases. It is, of course, possible that the author has not had experience with this simple service. If, however, he has, and does not think well of it, I for one would be very much interested to know why. It is less expensive, less bulky, and less annoying to the patient, and accomplishes the results aimed at far more perfectly than any other form of abdominal support. In regard to the letter of Dr. Rose in your issue of the 22d, I want to emphasize the following, viz., the gratifying results in cases of reflex vomiting, cough, and belching due to displaced stomach; the happy end attained in neurasthenic gastric cases, with one or more of the abdominal organs displaced. In many cases in which an absolutely clean-cut diagnosis is difficult, but in which the lower abdomen supported by the hands (in the position of the plaster) afforded immediate relief, one application has effected what might be termed a cure as far as symptomatology is concerned. Since the publication of my paper in *The Medical News*, I have used this support in upward of fifty cases. Recently a patient who had worn the plaster about two weeks returned to commend its work and to ask if when it "came off" she might have another applied. It was a case of ulcer with gastroptosis and double nephroptosis.

H. W. Lincoln, M.D.

Brooklyn, N. Y., December 23, 1900.

Gonorrhœa and Gynæcological Diseases.—Sanger states that in about one-eighth of all gynæcological diseases gonorrhœa is the underlying cause. Taylor, reviewing the condition from the side of the venereal specialist, says that this statement is conservative and probably nearly correct.

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, December 17, 1900.

PARKER SYMS, M.D., PRESIDENT.

Retention Cyst of the Liver.—DR. WILLIAM A. SHUFELT presented this specimen. It had been removed from a famous ballet dancer, who had first consulted him last July, complaining of pain in the hepatic region associated with jaundice. The stomach had been found markedly displaced downward. On the right side, just below the free border of the ribs, a movable tumor could be felt. The operation had been done one month later. The gall bladder was apparently normal, and there were no evidences of calculi in the common or hepatic ducts. The patient had made a rapid recovery, and the jaundice had quickly disappeared. Search through the literature had shown only five cases of simple cysts of the liver on record. The English authorities regarded these cysts as being sterile echinococcus cysts. The reason he did not think this one was such a cyst, but rather a retention cyst, was that he had been unable to find any trace of the echinococcus hooklets, and in addition it had been filled with bile, and its histological relations seemed to indicate that it was a retention cyst. There was a deep depression in the liver opposite the tenth rib, the result of excessively tight lacing.

Tube and Ovary in an Inguinal Hernia.—Dr. Shufelt also presented this specimen, which had been taken from a servant thirty years of age, who had been admitted to the Lebanon Hospital suffering from an irreducible inguinal hernia. She had suffered intense pain in it at the menstrual periods. She had never worn a truss. After the usual incision for the Bassini operation had been made the sac had been found to extend from the internal ring to a point well over the pubic bone. In the sac had been found a well-developed and normal tube and ovary. The fimbriated extremity of the tube was perfect. The ovary contained numerous fibroid growths, and was firmly attached to the sac. The tube and ovary were removed with the sac. The patient had made a prompt recovery.

Coffee as a Beverage, and its Frequent Deleterious Effects upon the Nervous System: Acute and Chronic Coffee Poisoning.—DR. WILLIAM M. LESZYNSKY read a paper with this title (see page 41).

The Verdict of the Human Race.—DR. WILLIAM H. THOMSON said that coffee was used by a very large proportion of the whole human race—roughly speaking, by about one hundred millions of people. This brought up the question as to whether coffee, tea, and tobacco were really poisons. His answer was emphatically "No," because they were used by all mankind on such a scale that if they were really poisons they would long ago have exhibited their ill-effects upon the various races of the earth. It certainly could not be said of any one of these that it really affected the health or the longevity of the human race. Physiological experiments on an unusually extensive scale had established the fact that to the majority of human beings, when healthy, these articles were in no sense deleterious. But it was a totally different question whether any of these agents, and coffee particularly, might not be very injurious to persons not strictly in normal health. In such persons almost any article of food or drink might become injurious. It was undoubtedly essential that the physician should carefully question a large number of his patients regarding their habit of drinking coffee.

Its Use and Abuse.—It was a striking fact that the races of mankind had uniformly adopted as habitual beverages plants containing caffeine or an allied chemical principle. This suggested that the ordinary and moderate use of such beverages could hardly be mischievous. He was of the opinion that coffee was of very great service to a multitude of people, acting as a relish, and enabling them to take a nourishing breakfast when otherwise they could not do so. This matter of relishes was an important and interesting subject, and had been elucidated by careful physiological experiments, having for their object the determination of the effect of such substances upon the gastric secretion. There were certainly some people who from idiosyncrasy could not take coffee at all without harm. In his experience these people were indicated to the physician by the fact that the taste of the coffee was "repeated" even when taken in moderation. Of course, marked excesses in diet, whether in coffee or in beef, should be checked, otherwise ill-health must result. He would invariably condemn the use of more than one cup of coffee at a meal. He was sure that a person using six cups of coffee daily for six months would exhibit symptoms which should indicate to the careful physician the necessity for checking this practice.

Coffee Drinking in Childhood.—DR. I. N. LOVE said that he had begun making special observations on the use and abuse of coffee about fifteen years ago, and had presented a paper on this subject about ten years ago to the Mississippi Valley Medical Association. There could be no question that coffee, tea, tobacco, and alcohol, though the last the least of all, were valuable as articles of diet if used properly. During childhood these articles should not be used at all. The carelessness with which parents would permit even babies to drink coffee was remarkable. This was often done through a desire to give the children a warm drink in the morning. The ill-effects of this practice were frequently met with by the physician. Such children early showed poor digestion and an irritability of the nervous system. He had been surprised to find how common this was, even among the well-to-do, and how seldom physicians gave the matter due consideration. He was of the opinion that this habit was a means of developing in these persons, as they grew older, a desire for something stronger. The exceptional individual of excellent inheritance and strong physique, and with a well-poised nervous system, could use coffee and tobacco from an early age without marked detriment, but it should always be borne in mind that these cases were decided exceptions. The child should have no stimulant, just as the thorough-bred colt should have no whip but oats or other wholesome food.

Coffee-Houses the Foe of Saloons.—Coffee, tea, and cacao contained practically the same active principle, but coffee contained the largest proportion of this substance—in other words, is the strongest. The psychical satisfaction produced by these beverages at meal-time was of much importance. Coffee-houses judiciously placed and managed would undoubtedly solve the saloon problem. Taken with the meal coffee was apt to disturb digestion. When he had desired to restrict the diet in the treatment of obesity he had advised the use of a cup of black coffee in the morning sandwiched in between two cups of hot water. When used in this way it stimulated peristalsis and favored digestion, at the same time that it removed the desire for food and enabled one readily to become a member of the "no-breakfast club." To obtain the best effect of coffee it should not be taken with the lunch or the dinner, but at three or four o'clock in the afternoon when there was no food in the stomach, and when fatigue was beginning to assert itself. The

after-dinner cup of black coffee was an example of the wrong use of coffee. Coffee taken as indicated by him, and without cream and sugar, acted admirably, and represented what should be the proper and habitual use of this beverage. The emergency use of coffee for night work was all right if done judiciously, that is, only as an occasional practice.

Coffee for Children.—Dr. Louis Fischer said that most pediatricians prohibited the use of coffee in childhood for the following reasons: (1) Because coffee was in no sense a food; (2) because it acted as a lubricant to the machinery of the body, and exerted its stimulating influence by toning up and diminishing nerve fatigue; (3) because it produced a disturbance of digestion by a direct interference with the chemical part of the process, producing an atonic dyspepsia; (4) because coffee was a cardiac stimulant, depressing the action of the heart when taken in large quantities; (5) because it produced choreiform movements, insomnia, extreme nervousness, night-terrors, and fear generally, and (6) because it was a diuretic.

Indications for its Use.—Coffee should be prescribed for children as a cardiac stimulant, but in very small doses. From one to several teaspoonfuls, repeated at regular and prescribed intervals, was the proper method of administration, and the physician should be guided as to the dosage by the effect on the pulse. There was no better cardiac stimulant for children than coffee administered in small doses along with large quantities of cream. As ordinarily taken, coffee consisted of an infusion of two ounces of coffee in one pint of water, and analysis showed that a cup of such coffee contained 1.7 gm. of caffeine and 3¼ gm. of gallo-tannic acid. For children coffee should be made of about half the usual strength.

Much Good in Moderate Coffee Drinking.—Dr. Albert L. Gihon said that we should bear in mind the fact that coffee, tea, cacao, kola, and other similar substances were distributed all over the world, and that there was not a race—savage, pagan, or civilized—that did not make habitual use of these things. It was a singular fact—almost a matter of predetermination—that these things should have been so widely distributed over the earth. It was also curious that they should all have nearly the same active principle. We should not confound use and abuse. Their almost universal and indiscriminate use should lead us to be cautious in drawing conclusions regarding the evil effects of such beverages. Aside from idiosyncrasies and a few exceptional cases, it seemed to him that coffee was useful, and was really a food. It was well known that most people took too much food, and if taking coffee in moderation would prevent this it might prove a boon to mankind. The use of kola in Africa was as beneficial in that country as the drinking of coffee was in many other countries. Kola might be called the king of them all. If coffee were good, then kola was better, but it should not be used more freely than coffee.

Dr. Leszynsky said that his paper had been presented after mature deliberation extending over a period of seven years. He had endeavored to eliminate all prejudice and to present a scientific contribution of a conservative character. He had not said anything therein in condemnation of coffee except when used indiscriminately and to excess, and it was because coffee was so commonly used in this country that he had felt impelled to write this paper.

Anatomical and Physiological Evolution of the Ovary from the Embryo to the Aged Woman.—Prof. John G. Clark, of the University of Pennsylvania, presented a paper on this subject, freely illustrated with lantern slides. He pointed out that the Wolffian body underwent complete atrophy and sank down into the pelvis, and that shortly after this a new set of vessels developed. If a testicle were to be formed from this genital mass, the vessels would be seen running up on top of the mass. The opposite was the case if the mass was to go to form an ovary. In the testicle the main circulation was on the exterior, so that any inflammatory changes going on within the organ would not specially impair the circulation of the organ. In the ovary the vessels divided into five primary branches, which ran into the centre of the organ, and spread out into numerous smaller branches. These marked differences in the circulation of the embryo ovary enabled one to differentiate at an early date between the sexes. The formation of the Graafian follicles was then explained, and each step shown by photographs. Attention was called to the arrangement of the vessels permitting in the developed ovary the perfect vascularization of even small portions under adverse conditions. The ovarian artery, it was stated, ran into the hilus of the organ and divided into two branches. Each one of these divided into about seven branches, and the latter freely anastomosed around the Graafian follicles. As the ovary was supplied with both the ovarian and the uterine circulation, there was ample provision for vascularization in case of injury. The follicles lying toward the centre of the organ having the best nutrition were in a state of great activity even in the young child, contrary to the usual opinion. The follicles did not wait until puberty to begin active ovulation, but it was only at that time that they reached the surface and could rupture and be fecundated. In an ovary from a child of two years one would find areas of scar tissue, showing the retrogressive changes which the follicles underwent in early life. A specimen from a girl of six years showed the centre, instead of being filled with myriads of follicles, made up of scar tissue, or rather of the connective-tissue stroma of the organ. The ovary from a girl of nine years showed a central nerve or vascular supply, and a sympathetic nerve supply on the periphery. The follicles were pushing up toward the surface. When they came near enough to the surface to make pressure on these sympathetic fibres and produce congestion, according to Dr. Clark's theory, the vessels became turgescent, and irritation of the surface resulted. The central vascular supply at this stage was not much disturbed. A photograph was shown of an ovary from a girl who had died of typhoid fever after having menstruated only once. It showed a very marked corkscrew arrangement of the vessels and congestion of the vessels. As a result of this circulatory change the follicle was pushed toward the periphery. He had made serial sections through the ovary, and had followed the individual arterial branches. Owing to the fine arterial branches at the periphery being at a right angle to the surface there resulted an area of poor vascularization on the surface where the follicle approached this surface, and this explained the occurrence of local necrosis. Very tiny cysts of the ovary were shown to be often strictly normal. The follicle was most apt to rupture one or two days prior to the appearance of the flow; hence impregnation was most likely to take place just before the flow. This opinion was generally accepted, the speaker said, by physiologists, and seemed to be based on anatomical grounds. Section after section was shown to give an idea of the very perfect granulating process by which, after menstruation, the ruptured follicle was filled up. The corpus luteum of pregnancy was the same as an ordinary corpus luteum except for the tremendous engorgement of the vessels. This probably explained why ovulation did not occur during pregnancy. When the artery was injected there was an almost immediate return through the vein. While, therefore, the follicles near the periphery were held in position, it seemed probable that the tremen-

dous vascularization of the corpus luteum of pregnancy deflected the circulation from the periphery and prevented other follicles from rupturing. As the woman grew older the follicles were situated farther and farther from the central or parent circulation of the ovary. The periphery became anæmic, so that even though follicles might still remain near the periphery they could not be brought to the point of rupture, owing to the diminished vascularization of the periphery. The vascular supply in the centre still remained good. The menopause did not come on as a result of the disappearance of the Graafian follicles, but rather as a result of the impairment of the circulation which was essential to the greatest development of these follicles. Graafian follicles were often quite numerous in the ovary even after the menopause, but the vascularization was not sufficient for rupture of the follicles to occur. It was well known that if the tiniest portion of an ovary were allowed to remain after an operation it would be sufficient to keep up menstruation for a short time. This was because of the splendid vascularization of the ovary. If the four main branches were ligated the remaining one could still maintain the function of the organ.

Dr. W. R. Pryor said that Dr. Clark was to be complimented, not only upon his indefatigable research, but upon his apparently convincing demonstration. Time and experience could alone settle some of the problems involved. There was hardly any room for criticism, yet perhaps many would not be willing as yet to accept in its entirety Dr. Clark's mechanical theory as to the establishment of menstruation and the production of the menopause.

Ovarian Transplantation.—Dr. Robert T. Morris said that for ovarian transplantation some surgeons were using nearly the whole ovary, while others were selecting only portions near the periphery. This matter of selection was a subject of much importance just at present, as well as the question of the most suitable site for making the implantation. Probably the best site would be that from which the original ovary had been removed. The wonderful study of the vascular supply of the ovary that had just been presented to the association had a very important bearing on ovarian transplantation. Some of the failures in transplantation might very properly be ascribed to too large a piece of ovary having been taken and an improper site selected for the implantation. In cases in which the uterus had not been fully developed in young animals, the uterus had gone on to complete development after ovarian transplantation, showing that the ovary presided to some extent over the complete development of the uterus. He asked Dr. Clark's opinion on these points.

Dr. Clark said he thought the success of ovarian transplantation depended not so much upon the blood supply as upon the lymph supply of the ovary. Until the organ could establish a separate blood supply it was probable that it was maintained in its new position by the lymph supply. For this reason he would suggest selecting the uterus itself about the broad ligament as the most suitable site. The chance of impregnation after ovarian transplantation seemed to him necessarily very questionable. The ovaries were frequently so completely encapsulated by adhesions that in spite of the existence of numerous perfect ova impregnation could not take place. This same barrier would be apt to be present in cases in which ovaries had been transplanted. In any case, ovarian transplantation opened up some extraordinary social complications.

Veratrum Viride is a perfectly safe remedy even when used in larger doses, provided the patient be kept in the recumbent position.—Coston.

WESTERN SURGICAL AND GYNÆCOLOGICAL ASSOCIATION.

Proceedings of the Tenth Annual Meeting, Held at Minneapolis, Minn., December 27 and 28, 1900.

The association met in the ladies' ordinary of the West Hotel under the presidency of Dr. O. Beverly Campbell, of St. Joseph, Mo.

A brief address of welcome, on behalf of the local medical profession, was delivered by Dr. James E. Moore, which was responded to by Dr. A. C. Bernays, of St. Louis, Mo.

After the transaction of routine business, the reading of papers was begun.

Insanity in Women Associated with Pelvic Disease.—A paper with this title was read by Dr. W. O. Henry, of Omaha, Neb. After briefly reviewing the current literature upon the subject and calling attention to the fact that very little was said upon it in any of the standard text-books upon gynæcology and mental diseases, he stated what appeared to him to be a fact, namely, that a large majority of all insane women had some pelvic disturbance as an important, if not a chief, causative factor. He then complimented the men who had done good work along this line, and had been courageous enough to follow it up, in spite of opposition and unbelief, and urged the bringing before the profession of the united testimony of all who had been giving this subject any special study, that the real truth might be arrived at, and suffering womankind be given the benefit of the very best the profession could offer. He then reviewed briefly sixteen cases from his own experience, of which ten patients were cured mentally and physically, three were improved, two were no better, and one died. He held that these all might have been saved by earlier and more radical local measures. He drew the following deductions: (1) Many patients operated upon but not cured, had failed of relief, either because attention to the local disease was not given early enough, or was not sufficiently radical. (2) Every insane woman should be given the benefit of a thorough and painstaking pelvic examination, and all pelvic disturbance quickly cured as an essential element in permanent restoration of the mind. (3) In some cases, when lacerations had been repaired and endometritis cured, there still remained enough reflex trouble from the uterus and ovaries, not perceptible until their removal, to continue the mental disturbance and demand their entire removal. (4) The general practitioner, as well as the laity, should be more fully alive to the connection between pelvic and mental diseases in women. (5) Many cases of insanity in women would be wholly prevented if the pelvic lesions were early repaired. (6) It was the duty of the profession, and especially of the general practitioner, into whose hands these cases first came, to urge upon women the importance of keeping the procreative organs in absolute health, and of having all injuries repaired early and diseases cured at once.

Hypospadias.—Dr. C. H. Mayo, of Rochester, Minn., followed with a paper on this subject. Hypospadias, he said, was one of the most common malformations of man, occurring in one to every three hundred to three hundred and fifty males. The varieties were balanic, penile, and scrotal, according to location. The older methods of treatment consisted of canalization, scrotal and penile flaps, denudation with suture, and flaps of the prepuce, or a combination of two or more of these principles. To these could be added mobilization and dislocation of the normal urethra. This (Beck) method of lifting the urethra from its bed and extending it to the end of the glans by a perforation or splitting of that structure

was an advance in the treatment of the glandular or balanic type of the deformity. However, three instances of Beck's method, reported from Czerny's clinic at Heidelberg, indicated that the contraction in each resulted in deflecting the glans downward, and that the delivery of the urine through the meatus was much as before. This would not occur in the slighter cases, and could be avoided in some of the others by tunnelling the glans in such a manner as to bring the meatus above the apex of the organ as a prophylactic against future contraction. The principle advanced by Van Hook, of a pediculated tube of urethra constructed from the prepuce and drawn through a tunnel in the penis and glans to meet the urethral opening, had been employed by the writer in two cases of perineoscrotal hypospadias, combined with bladder drainage by means of a Jacobs self-retaining female catheter through a buttonhole in the perineal urethra, and a urethral drain of strands of silkworm gut projecting from the new meatus and the perineal opening alongside the catheter. In the mild cases the urethra should be extended, and for the more severe cases a combination of this operation with that of Van Hook should be made, and a plastic closure at the point of contact would insure union by drainage of the bladder through a perineal buttonhole.

The Choice of Operations for Stone in the Bladder.—Dr. Byron B. Davis, of Omaha, Neb., read a paper with this title. He began by saying that the best operation for stone in the bladder was the one which most nearly answered the following conditions: (1) it had the lowest operative mortality; (2) it was followed by the smallest percentage of recurrence, and (3) it most nearly restored the urinary apparatus to a normal condition. He then showed that the operation of lithotrity had a small mortality, chiefly because it was used only in the comparatively simple and uncomplicated cases. In the hands of lithotritists the serious cases were treated by one of the cutting operations, and of course their results showed a large mortality. It was also shown that men who practised consistently the suprapubic method in all cases as they presented themselves, had a mortality which bore comparison with the results of the most skilled lithotritists. The number of recurrences were few when the cutting operations were practised and followed by drainage. Quotations from men with large experience showed that after lithotrity recurrences were very frequent, one in seven cases or oftener. In giving a reason for these numerous recurrences, the author found that after lithotrity the conditions which led to the formation of stone in the first place were not removed by the operation of lithotrity. The most frequent condition was stagnation combined with the presence of micro-organisms. Furthermore, it was asserted that no man could be sure he had emptied the bladder of all fragments and particles of sand, and these, if left behind, would serve as nuclei for fresh stones. On the other hand, when drainage was used after a cutting operation, until all infection had passed away, one of the chief factors in the production of recurrence was eliminated. Through an incision, all fragments could be easily removed; if the prostate obstruct, it could be dealt with in such a manner as to insure complete emptying of the bladder in the future. Dr. Davis operated in practically all cases by the suprapubic method. After removing the stone and doing anything called for within the bladder, he closed the suprapubic bladder wound, using superficial drainage to guard against infiltration of urine in the event of leakage. He then quickly established median perineal drainage, using a large catheter in the perineal wound, and maintaining careful asepsis until all indications of cystitis had disappeared. He concluded that (1) the mortality of lithotrity, when all classes of cases were considered, was no lower than that of the cutting operations; (2) the patient's condition after lithotrity was often no better than before; (3) recurrences were much more frequent after lithotrity than after the cutting operations with drainage; (4) lithotrity was not adequate to deal with the more serious and complicated cases, and the simpler ones would, most of them, end in recovery after any operation done aseptically.

Anæsthesia through Cocainization of the Spinal Cord; its Use and Limitation.—Dr. John B. Murphy, of Chicago, read a paper on this subject. Analgesia, he stated, was produced from the effect of the cocaine upon the sensory roots and ganglia within the spinal cord. The affinity of cocaine for the sensory nerve tracts was noted in the first experiments with this method. Reference was made to the researches of Corning and others. The speaker had been able to collect from recent literature 592 cases. Of this number, there were 4 partial failures, and 25 complete failures. Among the 592 cases there was only 1 death, this being partially attributed to the use of the drug, and was reported as having occurred in the clinic of Tuffier. Of the 5 deaths said to have occurred in Tuffier's clinic, the first 4 patients had died from other causes. The technique of the procedure should be very carefully carried out. First, the technique of preparing the solution was important; second, that of administering the proper quantity of the solution in the proper place; and, third, that of taking proper care of the patient afterward. The cocaine should be prepared by manufacturers who gave special attention to the sterilization of the crystals, etc. The dosage ranged from gr. $\frac{1}{20}$ to $\frac{1}{10}$ for children. Even gr. $\frac{1}{20}$ had been used in a child two and a half years of age. In adults the dose ranged from gr. $\frac{1}{6}$ to $\frac{1}{2}$. In his personal work the speaker had not used more than ♏ xv. of a two-per-cent. solution. Generally he used ♏ xii., many times ♏ xi., and very frequently ♏ x. for operations on the cervix, the vagina, and hemorrhoids; and for operations on the foot ♏ x. of the solution was sufficient. The symptoms, in the order of occurrence, after the injection of cocaine were great thirst, mental depression, and pallor. Vomiting rarely lasted more than a minute or two. In one of his own cases it lasted five minutes. Nausea may last longer. Nausea and vomiting had not been sufficient to disturb him in his surgical work. An important manifestation of the drug was elevation of temperature. After operations the temperature rose from 99° to 103° F., but usually declined before the next morning. In one case, found in the literature, it lasted for three days. In the forty cases in which he had used the method, there was only one in which he felt considerable anxiety. In this case the patient's face became pallid and the pulse very weak. The rule was for the pulse to decline or go below normal while the patient was on the table. The duration of the analgesia was sufficient in the majority of cases for any ordinary operation. In a case of osteotomy for a badly deformed femur the operation lasted one hour and twenty minutes, analgesia being complete during this time.

Post-Operative Fistula.—This paper was read by Dr. J. R. Hollowbush, of Rock Island, Ill. He stated that appendicular fistula might be external or internal; the material which escaped from the external type of fistula might be pus from an unhealed abscess cavity, or fecal matter from either the small or large intestine. The internal type of fistula was caused by the rupture of an abscess into one of the hollow viscera. The author reported cases of fistulæ following operations for appendicitis, biliary fistulæ, etc., and described a method of closing them.

Carcinoma of the Thyroid Gland.—Dr. A. E.

Halstead, of Chicago, read a paper with this title. He went exhaustively into the literature of the subject, saying that the study of primary carcinoma of the thyroid gland dated from a comparatively recent time. Cooper, in 1819, wrote that malignant disease of the thyroid never occurred, and cited many authorities to support his position. The paucity of early literature on the subject could be appreciated when it was considered that Lebert in 1862 found only twenty-three cases recorded, of which three were probably secondary growths. The results of operative treatment were not encouraging. Morris quoted Kuster concerning the outcome of fifty cases treated by complete or partial thyroidectomy. In eight, death followed within twenty-four hours after the operation; in five, within a week; in eight, within two weeks. Four remained free from recurrence for six months. Only one was known to be well at the end of four years. In the cases not operated upon, death resulted in most instances within one and one-half years, from suffocation, hemorrhage, thrombosis, or cachexia. In the cases reported by Poumet, Oser, and Lebert, death resulted from rupture of the carotid artery. In the case of Franque the immediate cause of death was thrombosis extending from the internal jugular to the heart. In the majority of cases death resulted from suffocation, from pressure on the trachea, or from collapse of its walls. Cachexia and infection caused death in only a few cases.

Symposium on Fractures.—This constituted the next feature of the programme.

The Pathology of Fractures. — Dr. Lewis Schooler, of Des Moines, Iowa, took up this part of the subject. He said that each case should be treated upon its merits, and the surgeon should have a thorough knowledge of all methods and appliances, as well as a knowledge of mechanical principles. The difference in the length and tension of muscles in the flexed and extended position of limbs was easily ascertained, and might be studied by any one. The difficulty with text-books and with legal requirements was a too strict adherence to former customs. These, in the eyes of the law and of many surgeons, were wisely and firmly established. Experience, however, showed their difficulties and their inability to meet the requirements in many cases. Even physiological causes might intervene and cause delayed union, as in the case of pregnancy, etc.

The Treatment of Fractures of the Neck of the Femur.—This paper was presented by Dr. John P. Lord, of Omaha, Neb. The writer stated he was of the opinion that no one method of treating these fractures could be adhered to, because various indications must be met. All were agreed in regard to the maintenance of efficient extension. It should be the aim of surgeons to reduce the deformity and to apply a dressing which would retain the fragments in constant apposition. The only exception to this dictum should be in cases in which extreme age or enfeeblement enforced relaxation of this vigilance. The writer was resolved to resort to Ollier's apparatus or a modified Phelps fixation appliance, as was done in orthopedic practice, when the next case presented its need, which would enable the attendants to place the patient in the upright position daily, or as desired. The author maintained that the old tentative methods of treatment so long in use did not apply to a large proportion of cases, and the old apprehension of hypostatic pneumonia and exhaustion from confinement in the aged did not have the same place as in days gone by, before the trained nurse and the masseur. Absolute fixation did not require so long a period of confinement as in the days of sandbags with extension of equally uncertain efficiency.

Observations on Compound Fractures.—Dr. D. S. Fairchild, of Clinton, Iowa, presented this paper. These fractures, he stated, came almost entirely under the head of emergency work and often occurred under the most unfavorable circumstances. The prognosis of an open, complicated, or compound fracture depended upon certain pathological conditions present, the chief of which was infection. The great majority of open fractures were made so by the traumatism which produced the solution in the continuity of the bone. In a certain number the fracture was made compound from within out by the sharp point of a fragment of bone, when the opening might be very minute, or the fracture might be made an open one in a few days by the separation of a slough due to the devitalizing influence of an external contusion with consecutive pressure from within or from without, or both. In these cases the healing of the bone did not differ materially from a simple uncomplicated fracture. Compound fractures caused by direct crushing violence were much more serious, in that the blood-vessels and nerves were liable to be involved, and the soft parts in general more seriously damaged. The question to be considered in fractures produced by direct violence would often depend on the nature of the force employed. In the late cases which came under the care of the surgeon the conditions would differ according to the nature of the infection.

The Ambulatory Treatment of Fractures.—This was discussed by Dr. Frederick Rustin, of Omaha, Neb. In selected cases, confined principally to fractures of the fibula, Pott's fracture, fracture of the malleolus and tarsal bones, the ambulatory treatment, he contended, was not only rational, but gave the patient the advantages claimed for this practice. Ambulatory treatment need not necessarily be immediate, but might be applied any time before the fragments were held in relatively firm position by the new growth which led to the callus formation, so that a period of seven to fourteen days might elapse after the injury, and yet the ambulatory treatment might be applied. The author described the different methods of applying splints. The advantages of the ambulatory treatment were: (1) The time which the patient saved, in some cases the period of incarceration being but a few days. (2) The swelling and œdema were less, owing to muscular action, and stiffness of the neighboring joints and muscular atrophy would probably be less, and union was apt to be hastened, owing to the fact that immobilization was not perfect, and irritation of the fragments stimulated a more hasty repair. The disadvantages were: (*a*) the callus formation was much enlarged, owing to imperfect immobilization; (*b*) embolic processes, of either fat or blood, were relatively encouraged; (*c*) immobilization was insecure, owing to muscular action, and finally non-union was not uncommon, particularly in people of advanced years. The author did not advocate the ambulatory treatment in all fractures, but believed there were certain cases in which it should be tried in justice to the patient.

Treatment of Fractures of the Skull.—By Dr. James H. Dunn, of Minneapolis, Minn. The treatment of these fractures, it was claimed, was essentially that of injuries to the cranial contents. Aside from the general management and care due to all serious head injuries, it consisted of prevention of infection, the control of hemorrhage, removal of foreign bodies and displaced fragments, and the relief or prevention of irritating lesions of the cortex. The ends to be reached were generally understood. To trephine in compound and depressed fractures, to open the skull on the development of focal brain symptoms following suspected or recognized fracture, under all circumstances to observe the utmost possible asepsis in the presence of an external wound or fissure of the base,

and to avoid operative intervention in the absence of clear indications, might be accepted as axiomatic. Experience showed that secondary trouble was unusually frequent in unrelieved depressed fractures of the skull, though the displacement might be but slight. Subsequent operations showed that proper exploration might probably have prevented the development of a cyst, abscess, or other serious secondary lesion. Operative intervention in head injuries was rational only in case a definite indication, both as to the probable character and especially as to the yet more probable location of the lesion, existed. If this reasoning be admitted, further progress in the treatment of skull fractures must lie in the direction of more careful general management, more accurate diagnosis, and an improved operative technique. The *x*-ray was not of practical value in the diagnosis of skull fracture, except in cases of metallic foreign bodies lodged within the skull.

Dr. C. C. Allison, of Omaha, Neb., read a paper in which he discussed "Hernia of the Bladder."

Dr. J. Clarence Webster, of Chicago, read a paper in which he reported "Three Interesting Cases of Cæsarean Section."

President's Address.—This was delivered by Dr. O. Beverly Campbell, of St. Joseph, Mo., who selected for his subject:

A Consideration of the Different Operative Procedures in the Treatment of Retrodisplacements of the Uterus.—In selecting a successful method of treatment for retrodisplacements of the uterus, it was necessary, he said, to note in each individual case the presence or absence of disease in the adnexa, as well as the mobility of the organ. Adhesions between the uterus and rectum in retrodisplacements were invariably the result of pelvic inflammation, which would have usually produced pathological changes in the adnexa. The author classified retrodisplacements of the uterus. Operative treatment should not be resorted to until after a reasonable trial of simpler methods of treatment. The chief objections to the Alexander operation were pointed out, as also the arguments in favor of it. The improved Alexander operation, whereby the inguinal canals were opened, adhesions broken up, and the appendages treated, was practised by the few. The objections to this method were referred to. After mentioning the various methods of shortening the round ligaments, Dr. Campbell described one which he had devised himself. An anterior colpotomy after Martin's method was performed and the fundus was delivered into the vagina. Each round ligament in its turn was drawn out of its peritoneal covering through an incision near its uterine attachment and held with forceps. An incision was made anteriorly through the peritoneal coat of the uterus, equidistant from the cornua and at a level with the attachment of the round ligaments. A pair of Spencer Wells' forceps was now passed beneath the peritoneal coat of the uterus and made to emerge at the uterine attachment of the round ligament. The drawn-out round ligament was fastened in the grasp of the forceps thus introduced, and drawn beneath the peritoneal coat of the uterus. The opposite ligament was treated in the same way. Chromicized catgut sutures, three in number to each ligament, were passed deep into the muscular tissue of the uterus and made to include the ligament. The rents in the peritoneal coverings of the ligaments and uterus were closed with fine catgut sutures. In completing the operation after his method of treating the round ligaments, no attachment was made of the peritoneum. The vaginal wound was closed with chromicized catgut sutures. Convalescence after anterior colpotomy was very rapid. The majority of his patients were allowed to sit up out of bed the twelfth day after operation, and given the freedom of the halls the fourteenth day. This was certainly not the case when ventrofixation or Alexander's operation had been performed. His operation was applicable to both the vaginal and suprapubic routes.

A New Intestinal Suture, with all the Knots Inside.—By Dr. F. Gregory Connell, of Chicago. He briefly reviewed the subject of intestinal sutures and classified the various methods of intestinal union as follows: (*a*) Foreign bodies: (1) Four Masters and modifications. (2) Invagination and modifications. (3) Senn plate and modifications. (4) Murphy button and modifications. (5) Special forms. (*b*) Suture: (1) Glover's and modifications. (2) Invagination and modifications. (3) Lembert and modifications. (4) Placing knots inside. (*c*) Miscellaneous. He drew attention to the gradual change which had taken place regarding the location of the knot of the stitch and emphasized the same in the following summary: (*a*) Outside of the abdominal wall; (*b*) outside of the intestinal wall, anchored to the abdominal wall; (*c*) outside of the intestinal wall, in free peritoneal cavity; (*d*) outside of the intestinal wall, buried between the serous coats; (*e*) inside of the intestinal wall, in the lumen on the mucosa. The author noted another change which had occurred during this gradual involution of the knot, and that was with reference to the amount of tissue included in the bite of stitch, which was strongly brought out in the following steps: (1) Suture including all coats with the knot on the serosa; (2) suture including peritoneum only; (3) suture including peritoneum and muscularis; (4) suture including peritoneum, muscularis, and submucosa; (5) suture (again) including all coats, with the knot in the lumen. He enumerated the different methods whereby the knots were placed in the lumen, but in none of which were all the knots so situated, even in the one method (Maunsell's) in which they were so placed at the site of the union; this was effected only by the aid of a second incision, which was closed with the knots on the serosa (Lembert stitches). The essential feature of the author's technique was the placing of the last knot in the lumen on the mucosa. The stitches were inserted in such a manner that the ends, the needle end and tail end, were free on the mucous coat, instead of on the serous coat, as in the ordinary stitch. The simple circular stitch, or the square stitch, might be so inserted. In order to tie this knot in the lumen, a threaded needle, eye first, was passed between any two of the previously inserted stitches, preferably about opposite the last stitch which was still to be tied, and the eye caused to emerge at the point where the threads or suture ends were still protruding from the lumen. The threaded needle and its thread formed a loop through which the free ends of the suture were passed. This loop, formed by needle and thread, was then withdrawn and, within its grasp, the two ends of the suture which were to be tied into the final knot. Traction on these threads or ends caused the bowel to flatten, as it were, thus bringing the mucosa of both sides in close contact, and while in this relative position the knot was tied, the ends were cut off short, and as the gut resumed its normal contour, that of a cylinder, the knot disappeared within the lumen, and the enterorrhaphy was complete. (The different steps in the author's method were fully illustrated in the *Philadelphia Medical Monthly*, January, 1899; also in the *Journal of the American Medical Association*, November 3, 1900, in which Dr. Franklin H. Martin reported the first case on the human subject.) The suture might be employed under any circumstances that the ordinary method of suturing was used in a continuous suture, as well as when interrupted stitches were used. The author claimed the following advantages by placing the knot in the lumen: (1) No foreign body.

Suture material would all pass away. (2) Early passing away of the suture material. (3) Decrease in adhesions to neighboring organs. (4) Perfect serous approximation. (5) Increased security. (6) Smaller diaphragm. (7) Less danger of necrosis. (8) Suture might penetrate all coats of the bowel wall.

Traumatic Injuries of the Ureter.—A paper on this subject was read by Dr. J. W. Macdonald, of Minneapolis. Ureteral injuries were divided into: (1) Subparietal injuries, or those in which no open wound communicated with the injured ureter. (2) Penetrating wounds, or those in which an open wound communicated with the injured ureter. (3) Surgical wounds, accidentally or intentionally inflicted. The most common causes of rupture of the ureter were pointed out; and the symptoms, diagnosis, prognosis, and treatment dwelt upon. Dr. Macdonald reported the following case, and presented the patient:

March 8, 1900, Miss O——, nine years of age, was dragged in front of the hind runner of a heavily loaded sled. Examination revealed no injury except a bruise on the right side. The patient was in great pain. No hemorrhage from any internal organ occurred at the time of injury or subsequently. The patient improved rapidly for four days and was discharged. The reporter was called again on the eighth day and found a tumor below the twelfth rib on the right side. This was opened with a lance and six ounces of a serous-looking fluid were withdrawn, which became nearly solid by boiling. The tenth day a trocar was introduced, drawing out about eight ounces of a similar fluid. The cavity was washed out with a strong solution of tincture of iodine. The sac refilled, and on the twelfth day a free incision was made, establishing free drainage. The discharge was examined and found to be urine. From this time until the performance of the operation by Dr. Macdonald, the daily flow from the side was about the same as by the bladder, and had every appearance of urine. There was but a slight elevation of temperature, but little pain after the first three weeks, and the health of the child did not appear to decline. The urine was found to be highly albuminous, containing more than one and one-half per cent. of albumin by weight. Urea was abundant, and a microscopical examination showed blood and pus cells. On June 7th he operated. An incision, beginning at the lower border of the twelfth rib and the outer edge of the erector spinæ muscle, was extended downward and forward about an inch in front of the anterior superior spinous process and ended about the middle of Poupart's ligament. The tissues were infiltrated to a considerable extent with pus, and exposure of the ureter was rendered difficult and in some places impossible by necrotic and by cicatricial tissues. The ureter was healthy for about three inches from the kidney, but here sloughing had taken place, and for several inches it was lost in a mass of cicatricial tissues. After a most tedious search, in which the writer opened into and closed the peritoneum at three different places, he considered further dissection was useless and removed the kidney. The patient made an uninterrupted recovery, and was now in excellent health.

Etiology and Pathology of Surgical Infections of the Kidneys and of the Cystonephroses.—This subject was discussed by Dr. M. L. Harris, of Chicago. In referring to the etiology, the author considered the manner in which the microbes reached the kidneys; the concomitant conditions which favored the lodgment and development of micro-organisms after they reached these organs, and the varieties of the microbe. He said there were four routes by which microbes might reach the kidneys, namely, through the blood stream; along the urinary tract; through the lymphatics by contiguity, and directly from without by trauma. The pathological changes, which varied according to the nature of the infecting microbe, were discussed, as was the particular part of the kidney chiefly affected. Pyelitis, pyelonephritis, tuberculosis of the kidney, cystonephrosis, pyonephrosis, etc., were dwelt upon at considerable length. Dr. Harris narrated the following case, which illustrated many points in the etiology of the various conditions considered by him.

Miss P——, aged eleven years. When two years of age she suffered from a severe intestinal trouble. Following the intestinal trouble she had pain in the left side of the abdomen and back. For a long time the pain was referred to the old intestinal trouble. After a few years the character of the pain changed. It became more paroxysmal, with freedom from pain in the intervals. During the paroxysms the pain was very severe, accompanied by vomiting and scarcity of urine. After lasting from one to two days there would be a rather free discharge of cloudy urine, and the attack was over until the next time. The urine contained a small amount of pus, a bacteriological examination of which revealed the colon bacillus. A diagnosis of intermittent pyonephrosis was made and an operation advised. At the operation the pelvis was found dilated to the size of an average orange. The ureter escaped from the lower part of the sac at its junction with the kidney substance. It then presented a rather sharp S-shaped flexure, and was bound to the sac wall by adhesions. The adhesions were separated and a plastic operation was performed on the uretero-pelvic junction, which restored a free opening into the ureter at the most dependent part of the sac. Primary union followed and complete recovery of the patient resulted.

The etiological points in this case were: A primary intestinal trouble followed by a colon-bacillus pyelitis. The inflammation extended through the wall of the pelvis of the kidney, with the formation of inflammatory adhesions which drew on the upper end of the ureter, causing the S-shaped flexure and fixing it to the wall of the pelvis. The contraction of the adhesions, with the formation of the flexure in the ureter, gradually produced an obstruction to the free escape of urine from the pelvis, and thus converted the pyelitis into an intermittent pyonephrosis.

Dr. W. H. Allport, of Chicago, followed with remarks on the surgical infections and cystic enlargements of the kidney, their symptomatology and diagnosis.

Treatment of Septic Infections of the Kidneys and Cystonephroses.—This topic was discussed by Dr. L. L. McArthur, of Chicago, who, for convenience of consideration, subdivided the treatment into (1) internal medication; (2) local applications (ureteral laverage and antiseptics); (3) surgical interference, either nephrostomy or nephrectomy. The author considered the use of certain well-known and often abused remedies in the treatment of septic infections of the kidneys. Reference was made to the alkalinity or acidity of the urine. As to the local treatment of renal infections, he could say nothing from personal knowledge, never having used lavage of the renal pelvis and ureter, either with or without antiseptic remedies, although excellent authorities had reported favorable results therefrom. Having determined the nature of the infection by bacteriological examination, and the involvement of one or both kidneys, efforts should be made to remove the source of infection; to destroy or inhibit the organism in question, and to provide free exit to the products of infection. If the infection had been by extension from a corresponding cystitis, vigorous and systematic treatment of that must be at once instituted. The choice of medicaments was not of so much moment as the systematic carrying out of

a rigid hygiene of the bladder. First, if the urine be acid, especially so with the gonococcus and bacillus coli communis, the urine should be rendered alkaline and the elimination from the kidneys of much fluid insured. Second, some of the better antiseptics should be given. The kidneys should be assisted by lightening their labors through good elimination from the bowels. As the bacillus coli communis was the most frequent cause of renal infection, it would be well to inhibit its multiplication in the intestines by intestinal antiseptics. Third, when, after a reasonable trial of these remedies, and the use of ureteral lavage *à la* Caspar, Albarran, and Kelly, the case progressed unfavorably, as the majority perhaps would, there remained nephrostomy. Every renal operation which could be done without opening the peritoneal cavity was the safer operation, especially so with septic kidney; hence the selection of a retroperitoneal route. Personally he favored the incision of a nearly transverse character, a finger's breadth below the last rib, and called attention to the possibility of making a muscle-splitting operation instead of a cutting one. It had not been the author's fortune to meet with many cases in which it seemed feasible or wise to deliver the kidney, as many operators recommended, external to the body, and he felt sure he had seen a death from too great traction on the pedicle of the right kidney, which, by constricting the inferior vena cava, cut off the return flow to the heart.

Dr. J. E. Summers, Jr., of Omaha, Neb., narrated an interesting case of adenoma of the tongue.

Dr. Alexander Hugh Ferguson, of Chicago, spoke of the various methods adopted by eminent surgeons for the excision of the superior maxilla, and then described a method which he had devised for removing the superior maxilla through the mouth.

The Operative Management of Retroperitoneal Abscess of Appendicular Origin.—Dr. Gilbert G. Cottam, of Rock Rapids, Iowa, read a paper with this title, in which he gave the following explanations of the occurrence of retroperitoneal abscess of appendicular origin: 1. Inflammatory attachment of the tip of the appendix to either fold of the mesocolon, followed by perforation into the post-colonic space. 2. Transmission of infection from an acutely inflamed appendix, situated anteriorly, along the lymphatics of the appendix and cæcum to the mesocolic glands. 3. Abnormalities of the peritoneal investment of the appendix. In about seventy-five per cent. of cases the meso-appendix was lacking, rendering the appendix an extraperitoneal organ, in contact with the peritoneum only on its anterior aspect. This type might be termed the retroperitoneal appendix and demonstrated its proximal relations to the post-colonic space. The various procedures available for reaching, evacuating, and draining retroperitoneal abscesses were given as follows: I. Anterior incision: (*a*) Transperitoneal. (1) Exploratory; if presence of retroperitoneal abscess was verified, immediate and complete suture of anterior wound and new incision made, as in II., or, suture of peritoneum only (Edebohls) and completion of operation as in (*b*). (2) Curative; evacuation and drainage anteriorly, with or without counter-incision posteriorly. (*b*) Extraperitoneal. II. Posterior incision. III. Incision per rectum, vaginam, etc. (chiefly of historical interest). After treating all of these in detail and describing illustrative cases, the author concluded by advocating the posterior incision in all cases in which a retroperitoneal abscess was suspected, or in which there was doubt as to whether the abscess was in front of or behind the posterior parietal peritoneum, for the following reasons: It did not open the general peritoneum; it allowed drainage by gravity; it permitted free exploration of the post-colonic space; it disposed of the hernia problem; and if the abscess should prove to be anterior, the iliac incision could still be used and drainage instituted through both openings, the lumbar incision then corresponding to the counter-incision as now ordinarily used.

Anatomical and Surgical Observations on Appendicular Abscess.—By Dr. A. C. Bernays, of St. Louis, Mo. The earliest operation of appendectomy in which he had found pus in the cavity of Douglas, he stated, was done on the morning of the third day, about fifty hours after the attack, and the amount of pus was over a pint. The large majority of patients were operated upon between the eighth and fifteenth days, *i.e.*, during the second week. He believed the most reliable sign of Douglas' abscess was the appearance of abdominal distention early in an attack of appendicitis. The treatment of appendicular abscesses did not come under the scope of the paper. The principles which governed the management and operation of these cases were well understood, and the selection of a method would be a matter to be determined in each case by the surgeon. The drainage per rectum in men and per vaginam in women of typical Douglas' abscesses was an easy and successful treatment in uncomplicated cases. In cases in which the Douglas' abscess was complicated by iliac, lumbar, or some other abscesses, or in which the Douglas' abscess reached so high that it could be felt above Poupart's ligament, it had often been opened and drained from the anterior abdominal parietes.

Dr. Van Buren Knott, of Sioux City, Iowa, gave a further report of a case of cerebral cyst upon which he had operated some three and a half years ago.

The Operative Management of Hip-Joint Disease: a Critique.—Dr. A. F. Jonas, of Omaha, Neb., read this paper, in which he drew the following conclusions: 1. The aim of surgeons should be radical in the removal of all affected structures and the preservation of all healthy bone. 2. The desire to preserve the greatest amount of healthy bone and consequently to insure the best possible joint function, made early incision imperative. 3. To insure the best possible function meant not only the early evacuation of intra-articular tuberculous products and the removal of diseased structures, but implied a most thorough disinfection. 4. The most effective disinfection method known at the present time was the application of pure carbolic acid and alcohol. It formed one of the most useful adjuncts. 5. The continued retention of the femoral extremity in the cotyloid cavity, which was necessary to insure good function, required the greatest possible obliquity of the upper end of the bone. This could be secured only by preserving as much of the neck as possible. When a portion of the neck was destroyed or must be removed, a certain obliquity could be obtained by removal of the trochanter major. 6. To insure permanent usefulness of the hip joint, long-continued mechanical correction by means of a portable extension brace must be insisted upon. 7. Excision of the femoral head, neck, and trochanter must be avoided when possible.

Symposium on Surgical Tuberculosis.—Dr. J. Clark Stewart, of Minneapolis, Minn., discussed tuberculosis of the fascia; Dr. Rollin E. Cutts, of Minneapolis, tuberculosis of tubes, ovaries, and peritoneum, and Dr. Knute Hoegh, of Minneapolis, tuberculosis of bones and joints.

Treatment of Tuberculosis of Bones and Joints.—This phase of the subject was discussed by Dr. James E. Moore, of Minneapolis. The treatment of tuberculosis of bones and that of joints were almost inseparable, he claimed, because the disease usually began in the epiphysis of long bones, and the neighboring joint soon became affected. Tuberculosis of the shaft of long bones was so rare that some surgeons

had never seen a case. When it did occur, the only treatment to be considered was the complete removal with hammer and chisel, and, in the absence of a mixed infection, allowing the wound to fill with blood clot. Bone chips, iodoform, and boracic acid were not so good as the blood clot. Orthopedists had arrived at great perfection in their methods, and knew just about what they could accomplish, but they were too well content with their methods and did not resort to operative measures soon enough. Their results were slow and unsatisfactory, but were better than the surgeon could offer at present. We must look to the surgeon for advancement, and when he had arrived at a greater degree of perfection, a larger number of cases would be considered suitable for operation. Early diagnosis was essential to good results from any treatment, and to this end every child who limped or complained of a pain in a joint should be subjected to a thorough examination. Every case of joint tuberculosis was best treated for a short time by rest in bed, with extension by weight and pulley. An apparatus applied later should afford rest and protection to the joint, and should hold the limb in proper position, since a tuberculous joint once cured in a faulty position could not be broken up safely. Plaster of Paris would yield better results in inexperienced hands than complicated braces. It should be applied just tight enough, be not too heavy, and should extend far enough above and below the joint to prevent motion. When joints of the lower limbs were affected, crutches, with a high shoe on the well foot, should supplement the plaster bandage. The injection method of treatment was not recommended. When a joint was growing worse, in spite of good mechanical treatment, it should be operated upon without delay. Pure carbolic acid and the actual cautery were recommended as valuable aids in operative cases. The writer believed that joint tuberculosis should be considered a local disease, and that an effort should be made to prevent its becoming general. Whether the disease be primary or secondary, it could be cured by complete removal. The surgeon should be as careful to remove all diseased tissue as if he were operating upon malignant disease. If extensive disease could be removed, saving life and a crippled limb, why could not surgeons operate early, remove the diseased focus, and save life, a good limb, and untold suffering? The mortality rate from early operation should be less than from present methods. Immediate results from early operations had been better than from any other method, but remote results had been bad because the growth centre was removed, causing subsequent shortening. It remained to be demonstrated that a joint could be opened at an early date, and the focus of disease removed without destroying the function of the joint or interfering with the growth of the limb. Bloodgood had been doing this at Johns Hopkins for some time, and he reported that his results were good enough to encourage him to continue.

Topical Applications in Gynæcological Practice; their Use and Abuse.—By Dr. J. W. Andrews, of Manakto, Minn. The author expressed himself as having very little confidence in the utility of pessaries and in topical applications in gynæcological practice. In a large majority of cases of retroversion or retroflexion of the uterus with tenderness in Douglas' pouch, he believed, there was some disease of the ovaries and tubes on one or both sides, and this could be cured only by surgical measures. In concluding his paper, he expressed the belief that there was no longer a legitimate field for the gynæcologist. There was no reason why a good surgeon who could operate well on the abdominal organs should not operate equally well on the pelvic organs. There was no reason why the general practitioner could not treat catarrh of the cervix, when it existed, as well as he could a catarrh of the throat. He hoped that the routine topical applications in gynæcological practice would be relegated to the mistakes of the nineteenth century.

Two Cases: (1) a Calcareous Uterine Fibroma, and (2) a Fibromyoma of the Urethra.—Dr. H. G. Wetherill, of Denver, Col., contributed this report. (1) This was a fibroid tumor of the uterus, one nodule of which had undergone complete calcareous degeneration. The tumor was a true fibromyoma in all its parts, except this particular nodule, which was quite symmetrical, entirely interstitial, and so infiltrated with lime salts as to appear like a mass of uncalcined limestone, and so dense as to require the use of a bone saw for making a section. Its diameters were four and three inches. The clinical history of the patient was like that of others with fibroid tumor, except for a notable record as to cancer. Her father, mother, two maternal aunts, and one paternal aunt had died of that disease. The patient recovered from the operation. (2) An operation for the removal of a tumor of the urethra and anterior vaginal wall, the tumor being a myofibroma and having its origin in the muscular coats of the urethra and completely enveloping that canal. The tumor was three and one-half inches long by two inches wide, and was first noticed twenty years before removal. It was reducible, but was not retained within the vagina unless resort was had to packing. The specimen was interesting chiefly on account of its rarity, the only other myoma of the urethra found reported by the author being one quoted in Kelly's "Operative Gynæcology." Examination of the tumor by a pathologist showed it to consist almost entirely of fibrous tissue, a few unstriped muscular fibres being scattered through the tumor. The author believed that the tumor had undergone much change during the long period of its existence, and that it was originally a true myoma, possibly of the leiomyoma type. It was necessary to strip the urethra of all muscular coats in the removal of the tumor, and the patient was troubled with imperfect control of the bladder contents after the operation, which a second operation failed to restore entirely, but which was re-established by a pessary made to supply the pressure formerly exerted by the tumor.

The following officers were elected for the ensuing year: *President*, Dr. A. F. Jonas, Omaha, Neb.; *Vice-Presidents*, Dr. A. W. Abbott, Minneapolis, Minn., and Dr. C. E. Ruth, Keokuk, Ia.; *Secretary-Treasurer*, Dr. George H. Simmons, Chicago, Ill.; *Executive Council*, Dr. O. B. Campbell, St. Joseph, Mo.; Dr. H. C. Crowell, Kansas City, Mo.; Dr. John P. Lord, Omaha, Neb.; Dr. James E. Moore, Minneapolis, Minn., and Dr. M. L. Harris, Chicago, Ill.; *Chairman of Committee of Arrangements*, Dr. John B. Murphy. Next place of meeting, Chicago.

Professor Fraser on the Plague.—Lecturing before the Royal Medical Society of Edinburgh recently, Professor Fraser said that the whole question of plague arrestation in India was one of sanitary reform, not restricted to providing windows to admit light to the houses, not restricted to the mere removal of accumulations of filth from the ground and neighborhood of the houses, or the cleaning of drains and the laying down of new sewers, but extended to a new form in house construction, not in an expensive form but in a simple form. He believed that it would be impossible to stop the plague in India till that was done. When that was done the house in India would, to some extent, be similar to the bungalow of the European in that country.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 5, 1901:

	Cases.	Deaths.
Tuberculosis	229	161
Typhoid fever	62	18
Scarlet fever	187	18
Measles	82	0
Diphtheria	283	51
Laryngeal diphtheria (croup)	8	0
Varicella	65	0
Smallpox	13	0

Plague in South Africa.—Telegrams from the Cape state that four cases of plague have occurred at King William's Town. The town is situated in the south-east district of Cape Colony, close to the seaport town of East London. The source of infection is not known, but the diagnosis is certain. At first it was stated that the patients had travelled from the neighborhood of the Madder River, but there seems to be no confirmation of the statement. We have from time to time been made acquainted with plague cases reaching South African ports, chiefly Cape Town and Durham, but fortunately so far there has been no sign of the disease gaining a footing in the Cape. The Durham instances were in immigrants from Tamatave in Madagascar, where plague has existed for some time.—*British Medical Journal.*

Vaccination in Paris.—According to the Paris correspondent of the *New York Herald*, vaccination has become quite a fad among the high society of that city. A fashionable doctor or the family physician is invited to a special vaccinal breakfast or afternoon tea, at which he makes an impartial distribution of lymph among the plump arms, or oftener still the shapely legs, for in order not to risk the little inflammation incompatible with décolleté dress many ladies prefer to be vaccinated in a more modest spot. "Preferrez-vous au-dessus ou dessous de la jarretière?" asked a doctor the other day, just as he was about to operate upon one of his pair patients. "Plutôt au-dessous," replied the pretty Comtesse D—— absent-mindedly, "parce qu'au dessus cela se verrait." Her response is greeted with ripples of laughter in the salons that are not too puritanical.

Strychnine in Cardiac Weakness.—To obtain the best results from its administration in heart weakness, strychnine must (1) be given in small doses, because large doses, apart from the undesirable effect upon the entire spinal cord by raising the blood-pressure, immoderately increase the resistance to the heart's action long before they can come to its assistance indirectly; and (2) it must be employed at a time when the strength of the heart has not yet sunk too low. If Binz is right in stating that strychnine does not produce the elevation of the blood-pressure by stimulating the vasomotor centre, but by increasing its reflex irritability—and hence peripheral impulses are required to accomplish the contraction of the vessels—then the strychnine must fail us in that very state of collapse in which modern routine so often continues to use it as a last resort. We do, indeed, sometimes succeed, under conditions which it is easier to divine than to recognize, by its use to prevent or delay impending collapse: but when collapse has once set in, I am convinced the drug is of no good effect. Moreover (3) it must not be given even in moderate doses for too long a time, because, like digitalis, it may accumulate in the body. Physiologists and pharmacologists seem to be better informed as to the cumulative effects of strychnine than the clinicians. Lauder Brunton calls it "a cumulative poison, as it contracts the renal arteries and thus prevents its own excretion."—Dr. G. Baumgarten, *St. Louis Courier of Medicine*, October.

Pessaries.—Personally, I agree with Lawson Tait when he said: "I hate pessaries, and never use them when I can help it." I am not in a position to denounce pessaries as frauds, but I am in a position to confess that, as a pessary fitter, I am a failure. Repeated and conscientious practice has not enabled me to accomplish the feat of legerdemain necessary to securely and permanently balance a wabbling womb on a rocking support.—Dr. Stewart McGuire, *Virginia Medical Semi-Monthly*, November 23d.

A Difficult Hysterectomy.—Here commenced one of the most frightful experiences that I ever went through; one of those sudden thunder storms, which were so numerous that summer, had come up. It suddenly grew so dark that we could not see into the abdomen, the rolling and crashing of the thunder, the beating of the rain on the slates, and the flashing of the lightning on the polished instruments, made a scene fit for Dante's Inferno. The electric lights were turned on, when there came a sudden flash and rumble and every light went out. The lightning had struck the transformer and put out every light in the building. Minutes seem hours at such times. The assistant reported the pulse failing, and that there was only enough ether to last a few moments longer; and, although it was raining as hard as ever I saw it, one of the officers rode in his shirt sleeves four miles for more ether and got back in time.—Dr. Frank Blaisdell, *New England Medical Monthly*, October.

The Prevention of Puerpural Septicæmia.—1. When labor is about to begin, or as soon after as possible, one or more enemas of soap and water are to be given till the rectum is quite empty; then, 2, the patient is to have a warm soap bath—in a bath tub if one be available—particular attention being given to the cleaning of the external genitals and anus, and the creases and folds of the skin about the groins, abdomen, buttocks, and thighs. 3. The external genitals are then to be washed with a solution of bichloride of mercury 1 : 1,000; or of lysol 1 : 100; to be followed by clean, warm, boiled water. 4. A clean, dry, absorbent occlusion pad is now to be applied to the vulva, and when possible this should have been sterilized. 5. Clean washable clothing may be put on the patient and a clean, properly protected bed is to be made ready for her. 6. After the patient has been prepared she must not use the water closet when the bowels or bladder are evacuated, but should use a clean chamber vessel, or jar, or a bed pan. 7. After each evacuation the external genitals must be cleansed as before (No. 3) and a fresh occlusion pad must be put on. (Vulva pads are best made of cotton and gauze, and should be made and handled with clean hands only, and placed in clean receptacles. They may be burned when soiled).—Dr. H. G. Wetherill, *Colorado Medical Journal*, October.

Diagnosis of Ectopic Pregnancy.—There are no pathognomonic symptoms of tubal pregnancy, or of any other form of ectopic pregnancy. Usually, however, we find the following points: The patient gives a history of several years of sterility (many exceptions); she has missed a menstrual period, perhaps two of

them (numerous exceptions); she has noticed some unusual pains in the pelvis, which she will probably describe as boring, griping, or colicky in character, these pains being situated usually in the region of an ovary; she has, perhaps, within a few days of the time of consulting her physician had a more or less irregular hemorrhage; perhaps has discharged pieces of membrane which she supposed indicated an abortion, and consulted her physician with the idea that such is the case, owing to the hemorrhage and the pain, and the suspicion of an existing pregnancy. Possibly, however, there has been no suspicion of a pregnancy, as the woman has accepted her sterility as incurable and has dismissed from her mind such a possibility. —Dr. J. F. Baldwin, *Courier of Medicine*, October.

South Sea Medicine Men.—Among the South Sea Islanders no man falls sick or dies from natural causes. They would argue, if they were called upon to analyze their belief, that health is the natural condition, and that every departure from it must be caused by supernatural agency, and since disease is an evil, you must look for its agent among those who wish you evil. Thus far they are at one with many good people in Europe who take comfort in the thought that every visitation of sickness is a divine judgment for their sins; but savages push their logic further. Their gods do no mischief for mischief's sake, and since all men have enemies, and are all free to invoke the unseen powers for either good or evil, the sick man has only to make his choice among the number of his ill-wishers, and charge his heirs to avenge him. Every skilled craft tends to specialization. A few successes in causing illness by spells gave a man a reputation as an expert. The unsuccessful found him ready to remove their enemies for a consideration, he took to the business as a profession, handing his secret down to his son, and his son's son, until the trade became hereditary. A family that once acquired it took good care not to lose it by bungling, as the "wise women" sometimes did, for the art of killing by witchcraft had this decided advantage over the art of healing, that if the spell failed there were other ways—a dose of something in the kava cup or a club stroke on a dark night. Thus among some of the Melanesian tribes it is not too much to say that the population is divided between the companies of them that caused disease and them that healed it. In Fiji leprosy was a special branch of the black art. No common wizard has the hardihood to pretend that he can compass it by the ordinary means of burying a lock of the victim's hair in a bamboo with incantations, and this is well, for even the most cunning healers admit that leprosy is incurable. The power of infecting with leprosy is hereditary in certain families alone. Their deified ancestors have become, as it were, leper gods, whose priests are the oldest living representatives of their stock. The evolution of the idea may be easily traced. Leprosy prevails in certain families, therefore the spirit of leprosy, which is the Fijian equivalent for contagion, is a sort of family retainer, obsequious to the commands of his hereditary masters, and since a living spirit must have a place to live in certain stones are pointed out as his shrines, and these are hedged about with a tabu that is never raised.

Camp Sanitation.—*The Hospital* says: "Two letters have recently appeared in *The Times* on the subject of camp sanitation, which strongly suggest that sanitary matters have not received that attention at the hands of the military authorities which they deserve. A regimental officer with the South African field force points out that in standing camps the water difficulty is, to a great extent, a matter of lack of careful supervision of the arrangements for filtration. All units are now provided with first-class filters, which, if properly attended to, are, he says, an inestimable boon. In numerous cases, however, these filters have been rendered useless by unfair treatment, becoming rapidly clogged up by the mud with which so much of the water in the South African rivers is highly charged; and he points out how easily this difficulty can be overcome by a preliminary straining. The fact is, the provision of pure water has to be taken seriously, and when we are gravely told that in standing camps in which filters are at work, it is 'impossible' to prevent our soldiers, so well disciplined in every respect, from helping themselves to water which is officially regarded as suspect, we cannot doubt that the task of protecting the water supply has not been undertaken with that sense of its importance which the subject demands. The necessity of placing the water under the guardianship not of a mere sentry but of an officer of some position and authority was one of the points insisted on when the subject of camp sanitation was discussed."

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended January 4, 1901:

		Cases.	Deaths.
Smallpox—United States.			
District of Columbia, Washington	December 15th to 22d	1	
Florida, Jacksonville	December 15th to 22d	1	
Illinois, Cairo	December 15th to 22d	3	
Chicago	December 22d to 29th	2	
Kansas, Wichita	December 22d to 29th	2	1
Nebraska, Decatur	April 1st to December 14th	416	4
N. Hampshire, Manchester	December 22d to 29th	14	
New York, New York	December 22d to 29th	11	2
Ohio, Ashtabula	December 22d to 29th	5	
Cleveland	December 22d to 29th	20	
Rhode Island, Central Falls	December 26th	1	
Tennessee, Memphis	December 22d to 29th	2	
Nashville	December 22d to 29th	1	
Texas, Galveston	December 17th	6	
Houston	December 22d to 29th	25	1
Utah, Salt Lake City	December 22d to 29th	52	
West Virginia, Wheeling	December 15th to 22d	3	
Wisconsin, Green Bay	December 23d to 30th	1	
Smallpox—Foreign.			
Argentina, Buenos Ayres	October 1st to 30th	22	14
Austria, Prague	December 1st to 8th	26	
Egypt, Alexandria	November 26th to December 10th	4	4
England, London	December 1st to 13th	2	
France, Paris	November 24th to December 8th	255	31
Greece, Athens	December 1st to 8th	1	
India, Bombay	November 21st to 27th	..	1
Calcutta	November 17th to 24th	..	8
Madras	November 17th to 23d	..	1
Italy, Licata	December 8th to 15th	..	1
Mexico, Vera Cruz	December 15th to 22d	..	1
Russia, Moscow	November 24th to December 1st	3	1
Odessa	December 1st to 8th	23	7
St. Petersburg	December 1st to 8th	5	3
Warsaw	December 1st to 8th	..	15
Scotland, Glasgow	December 15th to 21st	67	3
Yellow Fever.			
Cuba, Havana	December 8th to 22d	..	6
Mexico, Vera Cruz	December 15th to 22d	..	1
Cholera.			
India, Bombay	November 21st to 27th	..	2
Calcutta	November 17th to 24th	..	35
Madras	November 17th to 23d	..	1
Plague.			
India, Bombay	November 21st to 27th	..	58
Calcutta	November 18th to 24th	..	4
Japan, Osaka	November 20th to December 4th	4	
Madagascar, Tamatave	October 29th to November 18th	1	

Books Received.

THE MOSQUITO THEORY OF THE TRANSMISSION OF YELLOW FEVER, WITH ITS NEW DEVELOPMENTS.

BY CHARLES FINLAY, M.D.,

HAVANA, CUBA.

IN view of the admirable manner in which the army yellow-fever board is carrying out its investigation of my mosquito theory and the wonderful success which has attended all its steps, it may be of interest to the readers of this journal to recall the following extracts of a paper, dated December 31, 1891, which was never published in full, though some parts were utilized in another paper which I sent to the congress of Chicago in 1892. Apart from a modification of my views as to the manner in which the contamination of the mosquito is effected, already explained in a former issue of this journal (May 27, 1899), my ideas on all other points have not changed. In my paper of 1891 I said:

"The first idea of the mosquito considered as the habitual agent of the disease arose from the difficulty of accounting for the peculiarities observed in the propagation of yellow fever under any supposition but that of an infection produced by a natural inoculating agent which should, first, become contaminated from a yellow-fever patient, and, afterward, communicate the disease by inoculating susceptible persons with the germs that it had picked up and retained. This natural agent might or might not be present in a locality where a case of yellow fever was running its course; if present, the disease would be transmissible; if absent, the disease would not extend to other non-immune persons around the patient. The first step, under that hypothesis, was to discover such an agent, bearing in mind that, besides fulfilling the above conditions, it should likewise satisfy all those that are known to influence the propagation of the disease. . . . I have not been able to think of any other agent which could comply with those requisites except the tropical mosquito of America, and I must say that, so far, it has answered to the various tests to which I have submitted it in a manner far exceeding my first expectations. I must premise the statement that my investigations have been limited to the diurnal and crepuscular species of Havana, the 'Culex mosquito' (so named by Robineau Desvoidy, in 1817 or 1820, from specimens carried to Paris by the Cuban naturalist Felipe Poey), which I need not describe again, having done so in my previous papers. That species is the only one from which I have obtained a succession of stings (as many as twelve) in the course of the thirty or forty days that I have been able to keep them alive in small glass phials."

By the term "contaminated mosquitos" I understand such as have stung a yellow-fever patient within the first six days of the attack, and it is my belief that whereas one or two stings from mosquitos recently contaminated may either occasion in susceptible persons a mild attack of the disease or simply confer immunity without any perceptible pathogenic manifestations, a severe attack would result from a greater number of such stings, and the same might follow a single sting from a mosquito that had been fed exclusively on sweet juices during several days or weeks after its contamination, before being allowed to sting a non-immune subject. In this case the germs will have had time to develop more abundantly, and the virulence of the inoculation might be expected to become proportionately intensified. The climatic and topographical conditions which are known to favor the propagation of yellow fever may be reduced to three: temperature (70° to 90° F.), atmospheric moisture with proximity to the sea or to water courses, and low levels (never exceeding four thousand feet nor generally above a few hundred). The same conditions seem to be likewise indispensable for the vitality, functional activity, and reproduction of the "Culex mosquito." Being a hibernating insect whose functional activity can adapt itself only to tropical climates, it becomes benumbed and unable to sting when the temperature falls below 60° or 65° F., and it may thus remain in a condition of apparent death, from which, however, it will revive when the temperature is again raised to above 65° or 70° F., provided the refrigeration has not been carried to below the freezing-point. Moreover, the same limits, below 65° or 70° F., appear to impede the transformation of the larvæ into the winged insect. On the other hand, temperatures beyond 95° F. also deprive the Culex mosquito of its movements, and it dies at 105° or 110° F. When the insect is confined in an atmosphere artificially rarefied to correspond to altitudes of four thousand to six thousand feet, it is unable to fly, at least for a while, or to sting. If we consider the smallness of its wings it seems unlikely that the Culex mosquito will, of its own accord, fly to any considerable height or distance, especially when weighted by the blood which it has ingurgitated. These peculiarities agree with what is known about the propagation of yellow fever, its tendency to invade the lower stories of buildings in preference to the upper ones, and its non-transmissibility in places like the city of Mexico, Puebla, Petropolis, situated at considerable altitudes above the sea level. Finally, looking back from the earliest epidemics of the "peste" which decimated the Spaniards, on their first arrival in the tropical regions of America, to the modern accounts of yellow-fever outbreaks given by Laroche and by Barton, we find the abundance of mosquitos, while the disease prevailed, particularly mentioned.

Among the experimental data intended to prove that contaminated mosquitos do transmit the disease, I need only recall two of the cases described in my article in the *American Journal of the Medical Sciences*, Philadelphia, October, 1886. In Case I. (1881), a distinct attack of albuminuric yellow fever declared itself fourteen days after the application of a contaminated mosquito, the patient being the only one who took the disease among twenty soldiers under my observation, none of the others having at that time received the mosquito inoculation. In Case V. an unacclimated person while residing in a country place from which he had not absented himself since over two months, and in which no case of yellow fever had occurred for

at least seven years, was inoculated with a contaminated mosquito on the 18th of August, 1883, and was attacked on the 26th with a characteristic yellow fever of a mild type; only a doubtful trace of albumin was found on the fifth day, but the eyes were yellow and the gums bled; he remained thereafter permanently immune.

As a practical application of my "mosquito theory" to a test case, let us consider how far that theory might account for the facts observed in the propagation of the yellow-fever epidemic from Havana to Saint-Nazaire (France) through the *Anne-Marie*, in 1861, so admirably studied and described by Melier in his report to the French Academy. This explanation is. indeed. loudly called for by the circumstance that Bérenger-Féraud ("Fièvre Jaune," Paris, 1890) takes his stand against my mosquito theory precisely on the ground that the aforesaid epidemic cannot possibly be accounted for by my theory. Let us recall the facts:

The *Anne-Marie*, a wooden vessel with a crew of sixteen men, sailed from Nantes (France) for Havana, where it arrived on the 12th of May, 1861. During the thirty days that the vessel remained in Havana none of the men experienced any illness, beyond "malaise," fatigue, loss of appetite, or inclination to vomit. She left Havana for Saint-Nazaire (France) on the 13th of June with the same crew. At the start she remained twelve days becalmed in the Florida canal, with suffocating heat, frequent squalls, and heavy rains. On the 1st of July, two fatal cases of yellow fever and another (not fatal) the next day declared themselves on board. Two days passed without any new case, and then followed a series of six new invasions between the 4th and the 8th of July, none of them fatal, the last being the captain, whose attack was less severe, but was attended with a long and tedious convalescence. One, at least, of the other men, the mate, was certainly susceptible to the disease, and yet no other case occurred during the voyage. The vessel reached Saint-Nazaire on the 25th of July and was brought to the wharf, where she lay alongside of the *Arequipa*, another vessel then ready to sail for Cayenne (French Guiana). The captain of the *Anne-Marie* had left the ship to attend to his health, and the mate remained in charge of the vessel, while the rest of the crew got their discharge on reaching Saint-Nazaire, none of the men having taken the infection, as far as could be afterward ascertained. The unloading of the cargo was, therefore, accomplished exclusively by new men, under the mate's supervision. The hold was opened on the 27th of July, and the unloading ended on the 3d of August. The vessel, having been declared infected, was removed to the centre of the dock on the 5th and towed out into the open bay on the 7th, to be thoroughly disinfected. From the moment when the hold was thrown open, all the susceptible persons who entered it became infected with fatal yellow fever. On the 27th and 28th the cooper, who went down to inspect and repair damaged sugar boxes, the mate, and also five sailors belonging to another vessel who had gone into the hold from curiosity and picked out some sugar canes which were stowed between the boxes, all were attacked, a few days later, with yellow fever and died. Altogether, between the 27th of July and the 5th of August, nineteen persons who visited the hold or the deck of the *Anne-Marie* became infected with yellow fever. Five other persons appear to have caught the infection on the wharf or on the deck of other vessels in close proximity to the infected ship. Two persons in the town received their infection, apparently, through bundles that were taken to them directly from the *Anne-Marie*. A remarkable case was that of Dr. Chaillon, who never came to Saint-Nazaire at all, but on the 5th, 6th, 7th, 10th, and 11th of August had visited at their homes, in villages two or three miles distant from the port, four of the workmen who had been employed in the unloading of the *Anne-Marie;* he was taken sick with yellow fever on the 13th, and died on the 17th. This was the only second-hand infection that occurred, during that epidemic, on shore. More remarkable still was the case of Bruban, a stone-cutter, who never came to the side of the dock where the infected vessel was lying, nor had any communication (directly or indirectly) with it; he happened to be employed in repairs near the dock-gates while the *Anne-Marie* was being unloaded, at a spot distant two hundred and twenty-five metres from that ship. He was taken sick on the 4th of August, and died of yellow fever on the 10th. Finally, the *Arequipa*, which had been lying alongside of the *Anne-Marie* since the 26th of July, sailed on the 1st of August for Cayenne (French Guiana). Her mate, having apparently caught the infection from the *Anne-Marie*, was taken sick at sea on the 5th, and died on the 12th. A new focus of infection seems then to have developed on board the *Arequipa*, for a series of invasions occurred on the 22d and 26th of August, the 9th, 19th, and 20th of September, on her way to Cayenne, where the vessel arrived on the 8th of October.

The explanation of the above occurrences, according to my mosquito theory, would be as follows:

The *Anne-Marie*, when she left Havana, on the 13th of June, must have had three of her crew recently infected with the disease, the same who were taken sick on the 1st and 2d of July. During the operations of taking in cargo, provisions, and specially drinking-water, it is next to impossible that, at that season of the year, a considerable number of mosquito eggs and larvæ should not have been introduced on board. With the calms, hot weather, and rains that followed, a whole brood of new mosquitos must have been produced on board of the *Anne-Marie* by the time when the first cases of yellow fever declared themselves; the young insects by stinging those patients became contaminated, and some of them must have transmitted the disease to the next six men who were attacked, with a milder form, between the 4th and the 8th of July. At the time when these six men took their infection the calms had ceased and the vessel was moving more rapidly and had reached cooler latitudes, which circumstances (besides the attraction of the sugar) must have induced the mosquitos to seek refuge in the hold, entering it through chinks which were afterward found to exist between the hold and the quarters which the sick men had occupied. During the rest of the voyage the contaminated mosquitos would be feeding on the sugar and sugar cane, while the yellow-fever germs were multiplying upon their stings (?) and attaining their highest degree of virulence until the hold was opened on the 27th of July. The contaminated insects then commenced their yellow-fever inoculations upon all the non-immunes who came within their reach by entering the infected hold. The temperatures at Saint-Nazaire, from the 26th of July to the 4th of August, gave daily maxima between 69° and 77° F. (the latter only on the 1st of August), and minima between 53° and 63° F., from which it must be inferred that the mosquitos would leave the hold or fly out on deck or in the immediate vicinity of the *Anne-Marie* only during the hotter hours of the day; at other hours they would be benumbed in the open air, and might easily be conveyed in bundles or packages carried from the ship to their homes by the workmen employed in the hold. At the same time the range of temperatures was such that the reproduction of new generations of "Culex mosquitos" could not take place, so that all the yellow-fever inoculations at Saint-Nazaire must be attributed to mosquitos which had become contaminated on board of

the *Anne-Marie*, on the 1st or 2d of July (at any rate, within the first week of that month). The extreme term of existence, for that species of mosquito, being reckoned at from thirty-five to forty days, the youngest contaminated mosquitos imported by the *Anne-Marie* should have died within the second week of August; in point of fact, no instance of infection occurred at Saint-Nazaire that could be attributed to a later date. Dr. Chaillon's case may be explained on the supposition that some contaminated mosquitos, accidentally conveyed by the workmen returning to their homes, had stung the unfortunate doctor; those insects, however, having reached the natural term of their existence, would have been unable to continue the propagation of the infection. The case of the stone-cutter may be accounted for by admitting that, at the midday hours, some of the contaminated insects while flying over the deck may have been blown away by some gust of wind toward the water of the dock; in order to save themselves from drowning, they would have alighted upon any object floating on the water, which, drifting with the outflowing current, must have landed them close to the gate where the stone-cutter was working. The case of the *Arequipa* is instructive as showing how the climatic conditions on that vessel, arising from the fact that it happened to be travelling toward the tropical regions, must have enabled new broods of the Culex mosquito to develop so that a secondary focus of infection was originated, whereas at Saint-Nazaire the prevailing temperatures prevented the occurrence of this event. According to my theory, some of the mosquitos, free from contamination, must have passed from the *Anne-Marie* to the *Arequipa*, before the latter moved away from the side of the infected ship; they, probably, laid their eggs in some water-tank, communicated the disease from the mate to the next patient who followed (and died); a new brood of Culex mosquitos must have developed during the voyage and some of them, having found their way to the patients, occasioned the subsequent invasions on that vessel.

After giving the foregoing extracts from a paper written nine years ago, it is interesting to compare my former statements with the recent experience of th army yellow-fever board in their able investigation of the mosquito theory. Those gentlemen, undoubtedly, have placed beyond the possibility of a doubt the fact that the Culex mosquito, fasciatus, does transmit the yellow fever from the patient to non-immune persons so well isolated from other sources of infection that the severest critic must be satisfied that the characteristic attack which followed each of their five recent inoculations, with a constant incubation period of three and one-half to four days, was certainly the result of the inoculation. It is, moreover, worthy of notice that these remarkable experimental cases were obtained by an improved "technique" in perfect agreement with one of the statements contained in my paper of 1891, namely, that, whereas one or two stings from mosquitos recently contaminated may either occasion a mild attack of the disease or simply confer immunity without any perceptible pathogenic manifestations, a severe attack would result from a greater number of such stings, and the same might follow a single sting from a mosquito exclusively fed, during several days or weeks after its contamination, on sugar or sweet juices. The army board, however, were led to consider that a certain period of time must be necessary in order that the yellow-fever germs should reach the salivary glands of the insect, by analogy with what occurs in the case of the malaria germs after they have entered the stomach of the Anopheles; whereas my own inferences were the outcome of some personal observations and of the logical interpretation of the facts recorded at Saint-Nazaire.

Another important point which the army board, I understand, has undertaken to demonstrate experimentally, is the fact that other sources to which the yellow-fever infection has been hitherto attributed are absolutely incapable of determining an attack of the disease. Dr. Reed, Dr. Carroll, and Dr. Agramonte deserve, therefore, the highest praise and the gratitude, not only of their own nation but of humanity at large, for having carried to every scientific mind a conviction so pregnant with practical results.

January 1, 1901.

NOTES ON OVARIAN GRAFTING.[1]

By ROBERT T. MORRIS, M.D.,

NEW YORK.

Segments of thyroid gland transplanted to remote parts of the body continue to perform their function so well that it has come to be an established procedure on the part of some surgeons to engraft a piece of thyroid gland elsewhere in the body whenever the gland has to be removed from a patient. No matter whether the transplanted part is grafted beneath the peritoneum, beneath the skin, or beneath the mammary gland, it usually continues to perform its function so well that the development of symptoms of myxœdema is prevented.

Another matter of collateral interest to the subject of ovarian grafting which I wish to mention in a preliminary way is that of pregnancy after removal of both ovaries and oviducts. There are a number of well-authenticated instances of this sort, and I present the bibliography of the records of these cases in literature.

The term pregnancy after ovariotomy with numerous reports of cases is common enough in the literatures of the fifties, sixties, seventies, and eighties, but at this period there seems to be meant only single or unilateral removal of the ovary. Even as late as the time of the compilation of Gould's "Curiosities of Medicine" the subject of pregnancy after double ovariotomy did not attract enough attention to receive mention in that work, while pregnancy after single ovariotomy was regarded as singular enough for mention at some length. In 1890 Robertson briefly reports a case of pregnancy after double ovariotomy, and this seems to be the first recorded case, although two years before this time Wetherell reported pregnancy after a case of single ovariotomy in which the other ovary could not be found. We find nothing more on this subject until 1896, when at a meeting of the American Gynæcological Society Gordon reported two cases and Sutton one. In one of Gordon's cases he had performed a double ovariotomy himself, while there was some doubt as to the nature of the operation in the other case. Sutton had operated upon his own case. In 1898 Chambliss wrote to the editor of *The Alkaloidal Clinic* that he had known of a case of pregnancy following double ovariotomy. He had removed one ovary, and another operator had removed the other one. The editor said in this connection that he too had seen a case of the same sort. Ross, of Australia, reports a case of pregnancy after double ovariotomy, but in this case there is a possibility that the patient had become pregnant before the operation. Leonard has recently reported a case of pregnancy after double ovariotomy. In the present year Kossman, of Munich, has reported a case of pregnancy after double ovariotomy, which agrees with the experience of Robertson, Gordon, and Sutton in being complete and convincing.

The reason for these pregnancies after double ovari-

[1] A paper read at a meeting of the Society of Alumni of Bellevue Hospital, December 5, 1900.

otomy seems to be readily enough explained by an observation which I have made in one case.

On reopening the abdomen some months after a double pyosalpinx operation, a small portion of ovary that had remained on the distal side of the ligature was found to have retained its vitality. The ligature is often placed snugly about the pedicle of the ovary, but so near to the ovary that when the latter is cut away a small segment of it remains behind on the distal side of the ligature. Operators commonly believe that such small segments of ovary on the distal side of the ligature disappear by absorption, but it is probable that they sometimes remain quite well nourished through adhesion circulation, or contact circulation, and do not at all need the original circulation by way of the broad ligament for maintaining their vitality. In these cases we must remember also that the ends of the amputated oviducts may open shortly after operation, because mucous surfaces do not become adherent under the ligature, and the cases in which the ends of the oviducts remain permanently closed are ones in which plastic lymph from the muscularis and peritoneum has sealed over the ends of the closed mucous tubes. In any event, we know that the oviducts commonly open a few days after a ligature has been placed about them.

The two facts of retained vitality of transplanted thyroid gland and of accidentally transplanted segments of ovary give sufficient ground for experiments in transplanting ovary.

My experiments were begun in 1895, in the hope that ovary transplanted to a patient who had to lose her ovaries would at least give the benefit of the internal secretion of the ovary, with an avoidance of precipitate menopause. There seemed to be a possibility also that pregnancy might occur after deliberate transplantation of ovary, as well as after accidental transplantation of ovary, assuming that the cases of pregnancy after double ovariotomy were really ones in which ovarian tissue at the distal side of the ligature had retained its vitality.

At about this time there was a movement on the part of several members of the profession toward sacrificing uteri in cases in which the adnexa had been removed, on the ground that such uteri were useless. It was my hope that ovarian grafting would put a stop to this method of procedure in most of the cases for which it was advocated.

My first note on the subject detailed the histories of two patients, one who became pregnant after ovarian grafting, but who aborted; the other of menstruation in a girl with rudimentary uterus and adnexa who had not menstruated previously. This report was published in the *New York Medical Journal* for October, 1895. In May, 1896, Knauer, of Vienna, published a contribution upon the same subject in the *Centralblatt für Gynäkologie*, detailing experiments on rabbits and successful results as far as obtaining continued function of the transplanted ovary was concerned. He later published reports of cases of pregnancy in rabbits after transplantation of ovary. Since the date of my first two papers on the subject of ovarian grafting various authors have made reports, and I have collected a résumé of the literature of the subject to date.

My own cases of ovarian grafting up to the present time number twelve. I had expected to have opportunity to collect data from a much larger number of patients, but it has seemed best to state to patients the experimental nature of the work, and they have usually been reluctant to take an interest in the matter in the cause of science.

Two of the twelve cases are of very recent date; of the remaining ten, some have been lost track of, as they were pyosalpinx cases, and in the class of patients who are apt to have pyosalpinx. These patients had menstruated during the time that I could keep them under observation, but that fact in itself was not of great value, as many patients continue to menstruate for some months after the ovaries have been removed. It may be that these cases of persistent menstruation are sometimes cases with retained ovarian tissue.

The patients whose cases seem to offer testimony of value are the following, the first two of which have been previously reported:

Case I.—Mrs. J. F.——, Jr., aged twenty-six years, not pregnant in two years of married life. Septic tubal disease of long standing had practically obliterated the ovaries and tubes, leaving the pelvis filled with dense adhesions. There was chronic metritis. Remnants of tubes and ovaries were removed, together with masses of pyophylactic tissue. A small piece of the patient's ovary was transferred to the interior of the stump of the right oviduct (saline solution transmission). The patient became pregnant shortly after leaving the hospital about a month later, but lost a well-developed fœtus by abortion at the third month, presumably because of the presence of persistent pelvic adhesions. This result means that we are to be very conservative in the treatment of some of the uteri which operators are at present wishing to remove on the ground that such uteri are useless after the adnexa have been removed. I saw this patient in May of the present year, and she stated that menstruation had recently ceased, although she had menstruated with fair regularity for more than four years. The graft which I had introduced was probably too small to last for a long time.

Case II.—Miss L. B——, aged twenty years, had an infantile uterus and rudimentary adnexa. She had never menstruated, and had suffered from the common symptoms of suppression of menstruation. She received an ovarian graft in the fundus of the uterus from the ovary of a patient aged about thirty years. Eight weeks later she menstruated for the first time in her life; menstruation was profuse, lasting for ten days. A second menstruation occurred six weeks later, lasting for five days, and was normal in character. The third menstruation was five weeks later, scanty, and lasting for one day. The fourth and fifth menstrual periods occurred at intervals of four weeks, and were normal in character. The patient has made a great change for the better in personal appearance, and is relieved from her former distress. I have recently seen this patient, more than four years after operation, and she states that she occasionally misses a month, but usually menstruates at quite regular dates and in a fairly normal way, but menstruation is sometimes prolonged and sometimes is brief.

Case III.—Miss G. T——, aged twenty-two years. I had previously removed a large ovarian cyst of the right side. In December, 1899, I removed an ovarian cyst of the left side recently developed. The patient had suffered with irregular, scanty, and painful menstruation for some years. I grafted into the left broad ligament a part of an ovary taken from a patient a few years her senior who was subjected to operation for retroversion of the uterus, and who willingly furnished the graft from one of her ovaries. The physician of Miss T——, Dr. T. E. Pennington, writing under date of November 20, 1900, says that "since March, Miss T—— has menstruated regularly every month, the menstruation lasting the usual time, full, free, and easy. The patient says that she menstruates better in every way than since her first year of menstruation. I consider her case a very successful one."

Case IV.—Miss J. H——, aged thirty years, for several years had suffered from such painful menstruation that she was nearly incapacitated for work. Menstruation was scanty and irregular, accompanied

by severe pelvic pain, spinal irritation, and fainting spells. I made a diagnosis of ovarian sclerosis and informed her that I was loath to remove ovaries in a case of this sort unless the patient was fully aware of the consequences and voluntarily requested the operation to avoid invalidism. I operated in May of the present year, removing the ovaries and grafting into the broad ligaments segments of an ovary from a patient of her own age who was subjected to operation for retroversion of the uterus and who allowed me to take a part of one ovary for Miss H——.

A microscopical examination of the ovaries from Miss H—— by Dr. H. T. Brooks showed intense fibroid changes with very pronounced cystic formation and cellular infiltration. There were but small areas of unaltered tissue and rarely a follicle. The condition was one of fibroid induration with cystic degeneration.

Miss H—— writes me in two letters, the last one November 25, 1900, that she has menstruated regularly since the operation, with the exception of the months of August and September, and at this time she was ill with what Dr. J. F. Erdmann believes to have been pelvic thrombo-phlebitis. Just why such a complication should have occurred at that late date is a cause for speculation. Miss H—— says that with the exception of this incident she has menstruated regularly and freely; she feels perfectly well and has regained health and strength, weighing forty pounds more than at the time of her operation. She says that she has lost the pelvic pain and spinal irritation and the fainting spells, and feels better in every way. A part of the good result is due to the removal of sclerotic ovaries; the part referable to menstruation since the operation is apparently due to the ovarian grafting.

Case V.—Miss L. E. B——, aged twenty years. The case was closely similar to that of Miss H——. Operation on May 17th of the present year. A part of one of her own ovaries that looked normal and that was not involved in much cystic degeneration was transplanted, after removal, into the broad ligament of the left side. The patient writes under date of November 15th that she did not menstruate until the 30th of September; menstruation continued fourteen days with very little pain; she menstruated again on the 5th of October with much pain. Her third menstruation, November 5th, continued ten days with very little disturbance in comparison with what she had always suffered before operation. She says, "Grafting certainly has helped make menstruation easy." I regret that at the time of this operation there was no opportunity to engraft healthy ovary from another patient, and it was necessary to do the best that we could with a small piece of her own degenerate ovary.

Case VI.—Mrs. J. H——, aged twenty-six years. Chronic septic tubal disease with ovaries and oviducts enmeshed in dense adhesions. The patient was an invalid with severe dysmenorrhœa. I separated the adhesions and found it impossible to do conservative work in saving the adnexa. They were consequently removed, and a part of the right ovary was immediately transplanted to the right broad ligament. The operation was performed October, 1897. The patient writes me under date of November 21, 1900: "Menstruation is not painful as it used to be, but if I stand on my feet there is pain over the ovarian region. I am quite regular, but some months there is not very much flow, and at such times the blood seems to rush to my head."

The continuance of menstruation since October, 1897, indicates that at least the precipitate menopause was avoided by the ovarian grafting. The pelvic pain is probably due to re-formation of adhesions which filled the pelvis at the time of operation.

In ovarian grafting, I place the ovary that is to serve for a graft in a basin of physiological saline solution at a temperature of about 100° immediately on its removal. An assistant with thermometer and warmer saline solution at hand maintains the even temperature of the solution in the basin containing the ovary until all is ready for its transplantation.

In my early experiments ovary was sometimes grafted into a slit in the fundus of the uterus in such a way that the uncut surface of the ovary projected into the lumen of the uterus, and the raw surface of the ovary was sutured to the raw surface of the mesometrium, or else a segment of the ovary was grafted into the end of an oviduct. In later cases I have chosen the broad ligament as a site for grafting and as nearly as possible at the point that the ovary would normally occupy. By splitting the broad ligament and introducing the graft into the slit it can be sutured in such a way that the uncut surface of the ovary projects into the peritoneal cavity, while the raw surface of the ovary is in contact with the raw surface exposed by splitting the broad ligament. This apparently offers the best opportunity for continued nourishment of the graft.

The best result in ovarian grafting in my experiments to date is the avoidance of the menopause. The patients have continued to menstruate in a sufficiently normal way to indicate that the grafts have retained their vitality.

My one pregnancy, like one of Frank's, was terminated by early abortion, but the several successful pregnancies that have been obtained in rabbits by other experimenters indicate that we may yet hope for fruitful pregnancy in women as a result of ovarian grafting.

The untoward results in my own cases have been one case of suspected thrombo-phlebitis; one case in which the piece of degenerate ovary from the same patient has apparently continued to undergo cystic degeneration, and one case in an irresponsible patient whom I cannot now find, who was thought to have had an extra-uterine pregnancy, but who was not operated upon for that trouble and who disappeared. The possibility of extra-uterine pregnancy must always be considered in cases in which fimbriated ends of the oviducts have been removed, but in many of our cases we can spare the oviducts with the fimbriæ intact.

A brief résumé of the results obtained by other experimenters in this field is here appended, together with a bibliography of the literature, which will furnish opportunity for extended reference.

Knauer made two series of experiments. The first had reference to transplantation in the original bearer of the ovary, and extended over a number of years. His second series comprised transplantation from one animal to another. The terms "homoplastic" and "heteroplastic" transplantation have been applied to differentiate the two classes of cases.

In his first group there were twelve experiments on sixteen rabbits. The ovaries were ligated off and implanted in part in the mesometrium or peritoneal fold which covers the horn of the uterus on the same side of the body, in part between the fascia and muscle of the abdominal wall. The result of his experiments was that more or less of the ovary persisted in its new locality and was not only nourished there but performed its function in a fully normal way, Graafian follicles developed, ova were expelled and were eventually shown to be susceptible of impregnation with resulting birth of fully developed young. It was further shown that such transplanted ovaries preserved their function for years. Knauer was also at great pains to show that the uterus and general genitalia underwent no atrophy after transplantation of the ovaries, and determined that fact by careful microscopical tests of these organs after the experiment animals were killed.

He found in experiments on young animals whose uteri were not fully developed that after transplantation of ovaries the uterus continued to develop, showing that the ovary presides to some extent over the growth of the uterus.

Rubinstein made twelve experiments on rabbits, in each of which the ovary was left free within the peritoneal cavity. In five it was sutured to the peritoneum. He does not go into the results at present, as they are to be published in the *Archiv für Gynäkologie*. He sums up by stating that whenever an ovary was successfully transplanted the uterus remained fully normal and showed no tendency to atrophy, but whenever the transplanted ovary was absorbed atrophy of the genitalia then followed.

Ribbert made exhaustive experiments upon guinea-pigs which he describes in great detail. In animals killed as late as the one hundred and thirty-fifth day, ova were found perfectly intact as to structure and were performing the function of ovulation.

Preobrajensky experimented with six pairs of rabbits to determine whether the ovary would preserve its integrity if transplanted into the male abdomen. All of these experiments resulted negatively.

Marchese made eight experiments. He exchanged the ovaries in two pairs of female dogs. One dog ran away; in the second the ovaries were found necrotic three months and ten days later. The third dog died of peritonitis in five days. The fourth, killed three months later, showed one ovary necrotic, while the other was normal to the naked eye, but contained no Graafian follicles.

It is evident that the methods chosen by the different experimenters have much influence upon the final results, and there is opportunity for all of us to perfect our technique.

Herlitzka made forty experiments on rabbits. In some cases the ovary was implanted in the female, in others in the male peritoneum. The animals were killed at various intervals afterward. Microscopical examinations by serial sections were made. The results were not constant in character. The author appears to have demonstrated that Graafian follicles in good condition were visible in a male rabbit forty-two days after implantation.

Arendt made fifteen experiments on nineteen animals, rabbits and cats. Eleven times he transplanted the ovaries of rabbits to the broad ligaments of the same side; twice he transplanted the ovary of one rabbit to the broad ligament of another rabbit. Twice he transplanted the ovary of a rabbit to the broad ligament of a cat, and vice versa. In his experiments transplantation was followed by atrophy of the entire genital apparatus, including transplanted ovaries.

Dudley reports a case of ovarian grafting in a patient aged twenty-one years who had menstruated twice at the time of the report after the operation. Menstruation has lasted three and four days respectively, and in a normal manner. In a recent conversation Dr. Dudley informed me that he has now several successful cases to report for menstruation data.

Fish experimented with twenty rabbits. He has been unable to prove that the function of ovulation can lead to conception, but states that his experiments are of too recent a date to determine this point.

Frank experimented on three patients, two with double pyosalpinx and one with cystic degeneration of the ovary, the parts of sound ovarian tissue from each patient being implanted into the uterus or the stump of the oviduct. In all three patients menstruation reappeared in normal fashion. There was evidence of conception in one case, but the patient aborted.

Glass transplanted an ovary from one woman into another woman who had lost her ovaries two years previously. He placed the healthy ovary as nearly as possible in its normal locality, operating by the vaginal route. The first menstruation was sixteen days afterward, lasting two days; then followed suppression of menses for six months, after which the flow reappeared with the patient in perfect health at the time of the report.

Grigorieff experimented with twelve rabbits by transplanting the ovary of each side to the broad ligament of the same side at a point near the uterine cornu. Four of the experiments are given in detail. The author states that after these transplantations ovulation and conception may occur as in the normal rabbit. In several cases in which the animals were killed, no degenerative changes are mentioned. In one case the transplanted ovary was somewhat diminished in size. The ovaries were found normal with Graafian follicles visible.

Jayle made a number of experiments, transplanting ovaries from one rabbit to another and from rabbits to guinea-pigs, and vice versa, but has merely announced his experiments without reporting results.

McCone reports experiments on thirty animals, grafting ovaries from one part of an animal to another part, or to a different animal. The ovary was sewed to the mesentery of the broad ligament, a pocket having been formed to receive the gland. In one rabbit both ovaries were removed, and one of the ovaries was grafted on the right mesosalpinx. The rabbit became pregnant and gave birth to three well-formed young. The rabbit was killed and the grafted ovary found to be flourishing at its new site, showing maturing Graafian follicles and corpora lutei. In one case the ovaries were removed from a female rabbit and the ovaries of a female dog implanted in their place, one on the mesosalpinx and the other on the omentum. Three months later the rabbit was killed—her uterus and tubes were large and healthy, and the ovaries of the dog had continued to perform their function as shown by the presence of maturing Graafian follicles.

A summing up of the testimony of the various experimenters seems to indicate that a properly transplanted ovary may continue to perform its full normal function and that we may not only expect to prevent the symptoms of the menopause after a patient's ovaries have been removed, but we may reasonably expect a pregnancy in a certain percentage of cases. I have little doubt that the recorded cases of pregnancy after double ovariotomy are cases of pregnancy from accidental ovarian grafting, a portion of ovary having remained on the distal side of the ligature, with establishment of adhesion circulation or contact circulation.

It is important for us to determine now just what method of ovarian transplantation gives the best opportunity for the ovary to continue its function. We need to experiment upon patients whose ovaries have been removed one or more years previously, and whose remaining genitalia are undergoing degeneration, to determine if regeneration can occur. This is not improbable if the ovary has such a presiding influence over the development of the uterus as has been shown in some of the experiments upon young animals. In all probability a certain proportion of the women whose ovaries have been removed in the past, could have had ovarian grafting done, either from a piece of remaining healthy ovary or from a segment of an ovary from another patient, the operations having been so timed that the one who was to furnish the ovary could have been operated upon at the same séance with the one who was to receive the ovary.

The special dangers to be anticipated from ovarian grafting would seem to be no more than the dangers from simple uncomplicated laparotomy. I have heard of a number of fanciful objections to ovarian grafting,

but the matter can be safely left to responsible members of the profession.

58 West Fifty-sixth Street.

[Note.—In 1895 Dr. Morris appears to have anticipated, practically speaking, all that has since been accomplished along this line. In his experiments he had successfully made a homoplastic and a heteroplastic transplantation of the ovary in human subjects. In the same year Knauer at the suggestion of Chrobak began his experiments on rabbits. In his first series he proved that the ovaries of rabbits could be transplanted on the bearer in various localities, could form permanent attachments, be nourished and ovulate. Somewhat later he was able to show that conception could occur from such ovaries, with the birth of normal young animals. The period of observation having extended over a number of years, he was once more able to show that the transplanted ovaries retained their original qualities permanently.—Ed.]

CASE OF THROMBOPHLEBITIS OF THE LEFT SIGMOID SINUS MASKING A LATENT BRAIN ABSCESS IN THE LEFT TEMPORO-SPHENOIDAL LOBE, BOTH ARISING FROM CHRONIC OTITIS MEDIA.

By CARL KOLLER, M.D.,

New York.

Frances S——, aged eight years, was admitted to the ear department of Mt. Sinai Hospital on August 21st, suffering from what was apparently infective thrombosis of the sigmoid sinus of aural origin.

History: As to the previous history the statements of the parents were conflicting. According to one of them, the child had a running ear in early childhood, with repeated recurrences of the discharge. According to the other, the trouble dated back only six months, when the left ear began discharging, unaccompanied by pain. No medical advice was sought. The ear was syringed with warm water and within a week the discharge stopped. Since then the child has been well until five days ago, when the present illness set in with pain in the (left) ear and with some fever but no chills. During this time the child vomited twice. Gradually the pain increased in severity. There was no discharge from the ear. The fever became higher and the child had a chill last night. This afternoon (August 21st) the patient was brought to the Mt. Sinai Dispensary (service of Dr. Meierhof), where a paracentesis of the drum was performed, without, however, evacuating any pus. While at the dispensary she had a chill at 3 P.M., and another at 6 P.M. at the hospital, to which she meanwhile had been transferred. This second chill lasted ten minutes. The temperature was 105.8°. During the same time she had a twitching of the lower extremities, especially the right leg.

Condition on admission: The patient is well nourished and intelligent; is fully conscious and complains of pain in the left half of the head, especially the occipital region, and neck. The mastoid is of normal appearance. The fossa mastoidea and tip are moderately sensitive to pressure, whereas the region behind the mastoid toward the neck and occiput is extremely sensitive and also slightly œdematous. Be-

low the angle of the axilla a few swollen glands can be felt in the depth; the region along the upper part of the jugular is sensitive to pressure, but no cord-like swelling can be distinguished. None of the other symptoms frequently found in thrombosis of the sinus are present. The drum of the right ear presents a normal appearance. In the left ear a paracentesis had been performed in the dispensary; accordingly the drumhead is dull, not tense, and very little congested, except for the membrana flaccida, which is considerably congested.

The ophthalmoscopic examination reveals the picture of beginning neuritis. The discs are intensely red and woolly, and the veins are congested and tortuous.

Diagnosis: Thrombophlebitis of the sigmoid sinus.

Operation (August 21st, 9 P.M.): As the first step the internal jugular was ligated, following the advice of some authors to have the ligature precede the curetting of the thromboid sinus, through which procedure particles of infected matter are apt to be disseminated into the general circulation.

In this preliminary step Dr. A. A. Berg was kind enough to lend me his assistance. Incision was made along the anterior border of the sterno-cleido-mastoid muscle in its lower half, and after preparatory steps, double ligature of the vein one inch above the root of the neck was made and the vein was severed between the ligatures. The vessel was well filled with blood apparently not thrombosed. Thereupon the opening of the mastoid antrum was performed in the usual manner. The surface of the bone was found of normal appearance and porous. A few cells contained a small amount of pus and granulations. The antrum, three-quarters of an inch deep, contained inspissated pus and granulations, which were removed. Then the sinus was freely exposed. A small part of the bone between the latter and the antrum was found discolored dark green. No pus or granulations were found upon the sinus (which speaks for a recent origin of the affection); its outer wall, of greenish-white color, offered to the finger more than the usual resistance. The aspirating-needle was introduced and drew off a chocolate-colored disintegrated pus of a very offensive odor. Now the skin incision over the mastoid and the one on the lower part of the neck were united; the jugular vein was followed upward and dissected up to the digastric muscle, at which level it was ligated. This piece of jugular was excised and measured two inches. The sinus was incised lengthwise and a grayish-brown disintegrated thrombus removed. The sinus was curetted up and down without restoring circulation. More bone was removed to expose the beginning of the lateral sinus and the horizontal part of the sigmoid as near as possible to the bulb of the jugular. During curetting into the lateral sinus bleeding followed, showing that the circulation had been restored; this was controlled in the usual manner by packing with gauze. Curetting down toward the bulb disclosed some more disintegrated thrombus and finally some bleeding. The stump of the jugular when incised bled also, thus showing that some of the tributary sinuses were not occluded (inferior petrosal, condyloid vein). It was, therefore, considered more prudent not to attempt the intended syringing through the lower part of the sinus and the stump of the jugular vein. The wound in the neck was sutured, leaving a drain in the lower angle. The upper end of the mastoid incision was also sutured. The rest of the wound was packed with iodoform gauze and a dressing was applied.

Subsequent course: The morning after the operation (August 22d) the patient looked well and was bright. Temperature at 8 A.M., 99.2°. During the day a slight ptosis and more pronounced puffiness of the region of the left brow and eyelid appeared, which increased during the day and spread also to the right side. On the following day this œdema (evidently due to ligature of the facial vein) gradually disappeared. It was also noticed that she was hoarse or rather that her voice had a metallic sound. No laryngoscopic examination was made, but on inspection of the pharynx the left tonsil was found swollen, and the veins of the pharynx were engorged. This hoarseness, which disappeared the fourth day, returned again later and was noticed more or less during the whole duration of her illness. The evening of the same day the patient had a chill lasting ten minutes, and the temperature rose to 105.2°. It was assumed that some part of the disintegrated thrombus had remained in the lower part of the sinus and that particles of it came into the circulation through collaterals (inferior petrosal sinus and condyloid veins), an assumption which was made very probable through the conditions revealed at the autopsy. Accordingly the attempt was made to remove this thrombus by carefully syringing upward through the stump of the jugular, which, however, was not successful at first. Two more chills were registered on the third and fourth days; they were of short duration (eight and three minutes), and the temperature was a little over 104°.

The attempts at removing the thrombus by careful irrigation were continued and were successful on the third day after the operation, when a soft thrombus was washed out from the lower part of the sinus by a current entering the stump of the jugular. This rinsing was repeated at subsequent dressings, with the result that after a slight chill on the fourth day following the operation no more chills were recorded. It should not be omitted to state that about that time inunctions with Credé ointment (on the limbs, about grs. xx.) were begun and regularly continued for some time.

The condition of the patient was fairly satisfactory. She was fully conscious, sometimes very bright and cheerful, sometimes morose and sullen, but not more so than an unruly child would be under conditions of a severe and painful illness. Her sleep was good and her appetite was fair. The temperature continued to show a septic character, but kept in moderate bounds, mostly between 100° and 102°, although it occasionally went down to 99° and sometimes reached 103°. The wound on the neck had closed by primary intention. A deep abscess in the upper part of the posterior triangle of the neck was incised and drained. This abscess was evidently due to a continuation of the thrombus phlebitis into the deep posterior cervical plexus through the condylar veins. In the wound the exposed dura, which looked sloughy in the beginning and secreted offensive pus, became clean under treatment with concentrated carbolic acid followed by alcohol, so that about the tenth day after the operation the whole wound over the mastoid showed a healthy granulating appearance. To this, however, was an exception. The tampons introduced into the antrum and also in the auditory canal were always malodorous, the pus having the odor characteristic of caries. However, the exploration and eradication of this focus were postponed to a time when the patient would have sufficiently recovered from the severe operation which she had undergone.

There was one ominous symptom, however, which made its appearance first on the sixth day after the operation (twelfth day of illness), when the pulse was noted to be irregular. Most of the time it was regular and in proportion to the temperature and corresponding to the age of the patient, but sometimes when taken during sleep it was considerably too low, for instance 84 with 102.2° temperature (on August 28th, seventh day after operation, thirteenth day of

illness), or 88 with 103° temperature on August 29th. Once it went down to 62 with 99.6° T. on August 30th. However, this retardation never lasted long and seemed to be of entirely passing character, but the irregularity of the pulse is frequently and conspicuously noted on the bed slip. With the exception of this occasional condition of the pulse the patient seemed to be doing well and appeared to be progressing toward recovery.

Toward the second half of the third week after the first operation the general condition of the patient seemed less satisfactory. She was morose and sullen, although her mind was always clear and her answers were always quick and intelligent. She was restless, did not sleep so well, complained frequently of intense pain in her ear and the whole left side of her head, and would purposely derange the dressing as in an attempt to relieve herself. The color of her face became more sallow and she was somewhat emaciated. Under these circumstances the exploration of the carious focus in the neighborhood of the antrum, which had been deferred, was undertaken (September 10th, twenty-sixth day of illness, twentieth day after operation). The new granulations filling the antrum were removed with the curette and so was some of the soft bone in the neighborhood. When the roof of the antrum was explored with a probe, the latter entered without any resistance through a small opening in the bone and in the dura into a large cavity extending upward and forward, situated evidently in the temporosphenoidal lobe. Thus the existence of an abscess in the temporo-sphenoidal lobe which had not given any symptoms was established. The same day the condition of the patient had further changed for the worse. She had a slight chill and vomited several times, became somnolent, was sometimes delirious, and passed her stools involuntarily. The patient had to be catheterized on account of retention of urine. All these symptoms showed clearly that the meninges had become more extensively involved, either directly through the extension of the encephalitis, or, what seemed more likely and was subsequently made almost certain at the autopsy, through oozing or perforation of the absess into the ventricle.

Operation for abscess: In the evening of the 10th of September (twentieth day after first operation, twenty-sixth day of illness) the patient was chloroformed. The posterior wall of the auditory canal was removed by means of chisel and electric drill. The median fossa was opened over the tympanus and the dura exposed to the extent of three-fourths inch square. In the dura at the site of the tegmen tympani (which had been removed) a small round opening about one-sixteenth inch in diameter was exposed; the dura did not show any signs of recent inflammation. The fistulous opening was enlarged, a thin greenish pus evacuated, the abscess cavity carefully rinsed with saline solution, and a drainage tube introduced. A dressing was applied.

The next morning the patient seemed somewhat relieved. Temperature, 99°; pulse, 100; respiration, 28. She was delirious in the morning, but became clear in the afternoon, recognized mother and nurse, and asked for a drink. The eye muscles were not paralyzed; the reflexes on the left leg were increased. Toward the evening the temperature rose again. She had a very bad night; was delirious and very noisy, in spite of narcotics. In the morning of the following day she presented an entirely changed appearance. She lay in stupor with the eyes wide open, divergent, and rolling, the pupils dilated, the head bent back, the face swollen and of livid color; respiration very frequent and labored; she often uttered inarticulate sounds. The pulse became more frequent and weak (rose from 150 to 190), the respiration more frequent and shallow (32 to 54). The temperature kept rising until at 7 o'clock P.M. it had reached 107.2°; at 8:40 the patient ceased breathing, on the twenty-eighth day of her illness and the twenty-second day of her admission to the hospital.

Bacteriological Report.—Case, Frances S——.

August 21st: Culture from external auditory meatus —bacillus mycoides (contamination).

August 21st: Pus from mastoid—spreads show streptococci and short bacilli decolorized by the Gram procedure (proteus?). Cultures show streptococci only. A spread from the thrombosed sinus shows the same as the spreads from the mastoid.

August 21st: A culture of blood in the excised part of the jugular vein was made; 3 c.c. of blood were used, in three tubes. The cultures remained sterile, after being observed seven days.

August 26th: A culture of blood was made, 5 c.c. aspirated from a vein of the left arm being used. Four agar tubes were inoculated. All remained sterile. Time of observation nine days.—E. Libman, *Assistant Pathologist.*

Autopsy.—Case of Frances S——, made September 12th, fifteen hours after death. The dura is moderately adherent to the inner surface of the cranial bones. Under the pia, along the vessels of the convexity, is an exudate, cloudy on the superior surface and distinctly purulent toward the base. There is a purulent exudate at the base over the tuber cinereum, corpora albicantia, optic tracts, and posterior perforated space. There is a thick, extensive fibrino-purulent exudate over the lower surface of the pons, medulla, and inner half of both lobes of the cerebellum. There is not so much exudate along the vessels of the other parts of the base as there is on the lateral surfaces of the brain. On lifting the brain up some greenish pus is found coming from the opening into the antrum. A probe passed into the antrum opening enters a cavity in the temporosphenoidal lobe, from which the pus is found to be oozing. About 10 gm. of pus escapes. When the brain is completely removed, the conditions are found as follows: On the under surface of the left temporo-sphenoidal lobe at the posterior and outer part is a small opening about 0.3 cm. in diameter, leading into a large abscess cavity in the lobe. The edges of the opening are gangrenous. Directly under this, in the dura, is an opening of the same size with a thickened infiltrated margin. This opening lies just behind the tegmen attici. The dura laterally and posteriorly to the opening is gangrenous for an area of 2 x 1 cm. On stripping up the dura there is found an area of granulation tissue 2 x 3 cm. on its under surface, to the outer side of the perforation. The perforation in the dura leads to a large defect in the tegmen tympani (which opening was made in part at least during the last operation). An examination of the bone shows that the pyramid is carious. The part of the sinus which runs posteriorly contains no clot and no pus. The part internal to the field of operation, running along the posterior border of the petrous portion of the temporal bone, is filled with a moderately thick pus. At its inner extremity is a small purulent thrombus. In the longitudinal sinus and in the left inferior petrosal sinus are white (fat-like) clots lying free in the lumen. The other sinuses are negative.

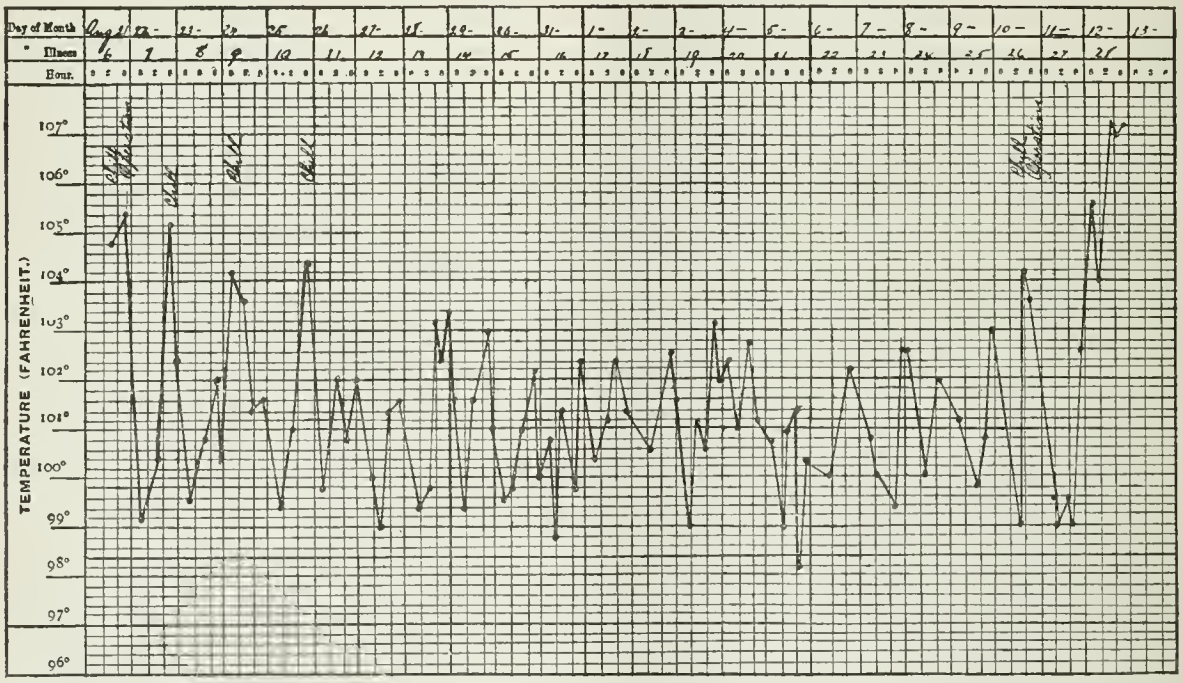
Examination of the interior of the brain: The right lateral ventricle is moderately distended (contains cloudy fluid). The choroid plexus and ependyma are much swollen. The third ventricle is not distended. The fourth ventricle is negative.

The abscess cavity in the left temporo-sphenoidal lobe communicates with the descending horn of the lateral ventricle. The abscess cavity measures 2.5–3 cm. in width, 4.5 cm. in length, height 2 cm. The abscess is not distinctly encapsulated, the margins are

necrotic and gangrenous. The pus is foul smelling. The choroid plexus is much swollen. The lining wall of the left lateral ventricle is softened and greenish in color, especially at the site of the optic thalamus.

Diagnosis: Caries of the pyramid. Thrombosis of the lower part of the left lateral sinus. Old abscess in the left temporo-sphenoidal lobe, communicating with the antrum through a fistula in the tegmen tympani. Purulent meningitis, secondary to perforation of the abscess into the lateral ventricle.—E. Libman, *Assistant Pathologist.*

Remarks: The facts of this case, and the history as far as it could be established, seem to indicate that the patient had been suffering from chronic otitis with occasional purulent discharge. It is true no perforation was found when she applied at the dispensary before her admission to the hospital and the tympanic membrane showed hardly any changes, but this is a circumstance occasionally met with in very extensive mastoid disease. The symptoms from which she suffered since the onset of her last illness were those of mastoid disease with infective sinus phlebitis and systemic infection.



To quote from Macewen's classic description: "The cessation of otorrhœa coincident with accession of persistent otalgia extending into cephalalgia, high temperature with marked fluctuations, vomiting and rigors ought to be regarded as pointing in the direction of thrombosis of the sigmoid sinus."

Besides these cardinal symptoms there are a few corroborating the diagnosis: the œdematous area behind the mastoid, the extreme tenderness of this region, the tenderness and slight swelling of the deep tissues in the upper part of the posterior triangle and the sensitiveness to pressure in the upper course of the jugular—all symptoms pointing to phlebitis of the veins connected with the sigmoid sinus: the mastoid vein, the deep posterior venous plexus of the neck, emptying into the condylar vein and the jugular vein.

The optic neuritis of low degree is likewise commonly met with in the beginning of the sigmoid thrombo-phlebitis. There was not a single sign on admission to indicate the presence of a brain abscess. Nor is this a rare occurrence. On the contrary, it might be put down as a rule that when sinus phlebitis is complicated with either brain abscess (if the latter is not too extensive) or with meningitis, the symptoms of an infective sinus thrombosis generally mask those of cerebral abscess completely and those of meningitis partially (Macewen, page 267). This is especially true of abscesses in the temporo-sphenoidal lobe, which, as a rule, do not produce any characteristic local symptoms. The production of hemiparesis on the opposite side (by involvement of the capsula interna) or of sensory aphasia (if the abscess be on the left side, as in this case), may be considered the exception rather than the rule. So that for the diagnosis of cerebral abscess one had to depend more on the general symptoms present in the initial stage of the abscess than on any focal symptoms. An abscess in the latent stage can hardly ever be diagnosed, especially when masked by sinus phlebitis. The terminal stage of abscess producing œdema of the brain with symptoms of brain pressure, or causing meningitis by reaching the arachnoidal space, or showing the dramatic symptoms of perforation into the ventricles, frequently elucidates a hitherto unclear clinical condition.

Considering the conditions found at the post-mortem examination, the abscess in the temporo-sphenoidal lobe was of longer standing and accordingly in the latent stage. Like in many cases of this kind it communicated through a fistulous opening (at the site of which brain substance, dura, and bone were adherent) with the middle ear, into which its contents occasionally drained themselves. The site of the bony erosion was, as is usual, the roof of the tympanic cavity. According to statistics made by Koerner, a fistulous opening connecting the abscess with the original focus in the temporal bone is met with in forty-two per cent. of the cases of brain abscess of aural origin. Although the autopsy made it appear most probable that the abscess was of long standing and the history of the last illness placed the accession of the sinus phlebitis five days back from her admission to the hospital, there is not a single circumstance which would make it probable that the abscess was caused by the sinus phlebitis. This is perfectly in accord with the statement made by Jansen[1] who expressly states that in none of his cases of sinus phlebitis complicated by brain abscess were there reasons found for assuming that the abscess had been induced by the sinus phlebitis.

[1] Archiv f. Ohrenheilkunde, vol. xxxv., p. 372.

From the course of the illness it is probable that upon the accession of the sinus phlebitis the hitherto dormant abscess was brought into a stage of irritation and progression. It is possible that this occurred without any outside interference; but it is also possible that the handling at the time of the operation and at the dressings caused the result. However this may be, in the second half of the patient's illness the symptoms of meningeal irritation became more pronounced. This irritation was most likely produced by oozing of pus into the ventricle until it terminated in real perforation; this latter, to judge from the characteristic and well-known symptoms, must have taken place less than twenty-four hours before death. The purulent meningitis found at the autopsy was caused either directly through the encephalitis reaching the brain surface or more likely induced by the pus oozing into the ventricles, whence it found its way into the arachnoidal space.

SUBARACHNOID COCAINIZATION IN OBSTETRICS AND GYNÆCOLOGY; A REPORT OF TWENTY-ONE CASES.

By N. J. HAWLEY, M.D., Superintendent
AND
F. J. TAUSSIG, M.D., Assistant Superintendent,
FEMALE HOSPITAL, ST. LOUIS, MO.

Much has been written on spinal anæsthesia of late, with reports of injections more or less successful, so the following contribution of additional cases may be of interest. Fourteen of these cases were obstetrical and seven gynæcological.

Concerning the technique of operation the important points are:

1. Surgical cleanlinesss in all things and a fresh, aseptic solution of cocaine, full strength. The method of sterilization used at the present time is to raise the temperature of the solution (in small bottles) to 80° C. for one hour on two successive days.

2. The needle need not be longer than 7 cm. and should be kept sharpened.

3. A nurse should stand at patient's head when the puncture is made to keep the back arched forward. A case was recently reported in this city of a patient suddenly sitting upright and breaking the needle.

4. During an operation the patient's ears should be kept closed with cotton and the eyes covered with a towel or cloth.

Following are the histories of the cases:

Case I.—M. J——, aged sixteen years, primipara. Labor pains began October 16th, at 8 P.M. Progress was slow. At 9:50 A.M., October 18th, the cervix was completely dilated and preparations were made to inject gr. $\frac{1}{6}$ cocaine into the subarachnoid space. Repeated attempts to find this space proved a failure, so the cocaine was injected into the tissues near it. After seven minutes had elapsed there was some hypalgesia of the legs and pinching the labia was not painful. Labor pains, however, were felt as such. This slight anæsthesia lasted only twelve minutes. The child was born twenty minutes later, the mother suffering severely as the head passed the introitus. This was the only case in which we failed to enter the canal. No toxic symptoms developed.

Case II.—D. D——, aged twenty-one years, primipara. Labor pains began at midnight October 21st. Position, O. L. P. The cervix was completely dilated at 3:45 P.M., when cocaine gr. $\frac{1}{3}$ was injected into the subarachnoid space. For about one hour thereafter uterine contractions were no longer painful. There was little progress during this time. Then pains returned as before. A second injection of cocaine was then given, amount gr. $\frac{1}{4}$. The resulting anæsthesia lasted for almost an hour. By 6:45 the head having made no progress, the forceps was applied. Only about gtt. xxx. of chloroform were necessary to relieve the pain of the application. The occiput had rotated to the sacrum. A small tear in the perineum was sutured painlessly with no further anæsthetic.

Case III.—E. N——, aged thirty-nine years, primipara. Labor pains began at 3 A.M., October 31st. Progress was rapid. Presentation O. L. A. The amniotic fluid was tinged with meconium when the membranes ruptured at 8:30 A.M. Two hours later the fœtal pulse had fallen from 138 to 96. Cocaine gr. $\frac{1}{3}$ was injected. Four minutes later under complete anæsthesia the forceps was applied and the head, which had already reached the perineum, extracted. The child was asphyxiated, but after a few minutes began to breathe regularly. The perineal laceration was sutured without any pain to the patient.

Case IV.—W. R——, aged twenty-two years, primipara. Labor began at 4:40 A.M., November 13th. After complete dilatation of the cervix, the pains became severe. At 1:36 P.M. cocaine gr. $\frac{1}{3}$ was injected. At this time the perineum was beginning to bulge with each pain. In six minutes after the injections the contractions were almost continuous and yet not felt by the patient. Unaided by the abdominal muscles, the force of the uterus was such as to expel the child's head in spite of the resistance offered by the physician's hands. Twenty-five minutes previous to the injection the amniotic fluid had been tinged with meconium and the fœtal pulse indistinct. The child was born in severe asphyxia and although it gave a few gasps, all efforts at resuscitation failed. The placenta was expelled one minute after the child was born.

Case V.—A. B——, aged twenty-five years, primipara. Labor began November 14th at 1:30 P.M. The cervix was completely dilated at 10 P.M. and the head seen almost on the perineum. An injection of gr. $\frac{1}{3}$ of cocaine was made. In four minutes the contractions became painless. These were not strong, however, and in spite of appeals the abdominal muscles were not used by the patient. At 1 A.M. the fœtal pulse had fallen to 110. As no progress had been made for two hours, a low application of the forceps was made. This procedure, as well as the subsequent perineorrhaphy, was absolutely painless. Complete anæsthesia lasted for thirty minutes after the patient was brought to bed.

Case VI.—A. M——, aged twenty-one years, primipara. Labor began November 18th at 3 A.M. Presentation O. L. A. The pains were light until the afternoon when the patient, a very excitable woman, became almost frantic and uttered wild cries with each pain. At 5:31 P.M. the perineum began to bulge and an injection of gr. $\frac{1}{3}$ was given. In three minutes the patient became perfectly quiet. Uterine contractions continued unfelt by the patient, but apparently were less powerful. The patient refused to bear down when told to do so and little progress was made. About one and one-half hours after the injection the patient again began to notice the contractions vaguely, and fifteen minutes later the pains were as severe as ever and she suffered as at first. The head had not advanced over an inch during these two hours, and a few whiffs of chloroform were now given with each pain until the birth of the child at 8:48 P.M.

Case VII.—R. McD——, aged twenty-three years, multipara. The pains started at 6:30 A.M., November 22d. The patient suffered greatly until 1:58 P.M., when she was given an injection of cocaine gr. $\frac{1}{3}$. At this time the cervix was almost completely dilated, Complete anæsthesia resulted for an hour, during

which time the contractions were unnoted and little progress was made. Finally two contractions, slightly painful, stimulated the patient to help and caused the expulsion of the child at 3 P.M.

CASE VIII.—M. H——, aged nineteen years, primipara. Labor began November 23d at 8 A.M. Progress was slow. Presentation O. D. P. At 9:30 P.M. that day the head had advanced to the perineum. The patient did not assist her pains well. Cocaine gr. $\frac{1}{4}$ was injected. Complete anæsthesia resulted in three minutes. The uterine contractions continued at the same intervals as before, but were not so effective. The abdominal muscles gave but little help. Five minutes after the injection the patient vomited and then became very drowsy. Her pupils were dilated, her skin was cold and clammy, and her pulse ran up to 124. At the same time the fœtal pulse fell to 100, but rose to normal again in ten minutes. After one and one-half hours had elapsed the patient again began to feel the uterine contractions as such, but they were not painful. No material progress having been made and the fœtal pulse again becoming slow, at 11:30 P.M. the forceps was applied. The patient experienced slight pain with the application, but not enough to warrant any further anæsthesia. The perineal laceration was sutured without pain.

CASE IX.—A. H——, aged twenty-six years, primipara. Labor began November 26th, 6 P.M. Position O. L. A. The head was seen at the vulva at 10:58 A.M., at which time cocaine gr. $\frac{1}{3}$ was injected. Anæsthesia was complete in two minutes. The contractions at once became less frequent and less powerful. Some nausea and vomiting occurred and were aggravated by pressure on the uterus. At ten o'clock the contractions became perceptible to the patient and stronger. The abdominal muscles were now called into play. By 1:50 P.M. the child was born with considerable pain to the patient. The suturing of the perineum also caused some pain.

CASE X.—M. D——, aged twenty-three years, primipara, began to suffer labor pains at 3 A.M., November 27th. The head presented at the vulva at 11:48 A.M. A lumbar injection of cocaine gr. $\frac{1}{3}$ was made. As soon as anæsthesia was established the patient refused to assist her uterine contractions, although the latter continued at regular intervals as before. The head slowly advanced until two o'clock. After this slight pains were again felt by the patient and progress was rapid, the child being born in twenty minutes. The perineorrhaphy was not painful.

CASE XI.—M. E——, aged twenty-four years, multipara. Labor began December 2d at 10:30 P.M. Progress was rapid. Presentation O. L. A. At 1:53 A.M. the cervix was dilated, whereupon gr. $\frac{1}{3}$ cocaine was injected. Anæsthesia was complete in seven minutes. The contractions were as powerful as before the injection and the child was expelled at 2:06 A.M. without a pain. The mother said afterward, "I had no pain after you put that morphine in my back."

CASE XII.—A. H——, aged twenty years, primipara. The pains started December 6th, 6 A.M. Slow progress was made in the first stage. Cocaine gr. $\frac{1}{4}$ was injected as soon as the head could be seen at the vulvar opening. At 11:18 P.M., thirty minutes after the injection, under complete anæsthesia and with persistent powerful contractions, the child was delivered. There was some asphyxia of the child, possibly owing to a knot in the cord. The perineum was intact. The anæsthesia continued thirty minutes after delivery.

CASE XIII.—G. M——, aged twenty-one years, multipara. Labor began December 3d at 6 P.M. The patient suffered a good deal and progress was slow for a multipara. Presentation O. D. A. At 11:25 the next morning cocaine gr. $\frac{1}{3}$ was injected. The contractions were painless, but were felt vaguely by the patient. At the time of the injection the cervix was completely dilated. The child was not born until 12:30. The anæsthesia lasted until 12:50.

CASE XIV.—K. S——, aged twenty-nine years, primipara. Labor was slow in the first stage, lasting from December 5th, 5 P.M., to December 6th, 3:45 P.M. Then cocaine gr. $\frac{1}{4}$ was injected. The contractions continued, but the head did not advance along the perineum. No pain was experienced with the uterine contractions until about 6:30 P.M., after which time there was still slight analgesia. No advance having been made by 8 P.M. and the mother being exhausted, a low application of the forceps was made and the child delivered. Some chloroform was given for this last procedure, as the patient complained of pain.

CASE XV.—B. S——, aged thirty-three years. Endometritis; hypertrophy of the labia majora. On October 20th, at 10:45 A.M., the patient being prepared for operation, gr. $\frac{1}{6}$ cocaine was injected into the subarachnoid space. In six minutes the pain sense was gone. After curettage, a small piece was excised from the cervix for examination. All this was absolutely painless. Then the labial tumor was extirpated. The operation was finished at 11:15 A.M. The anæsthesia, which had at first extended to the umbilicus, began to disappear toward the end of the operation and the patient complained of pain as the last few sutures were inserted.

CASE XVI.—A. H——. Condylomata acuminata. On November 13th at 10 A.M. cocaine gr. $\frac{1}{4}$ was injected. In five minutes we began cutting away the very profuse condylomata about the anus and vulva, with practically no pain to the patient. Anæsthesia became complete and remained so for over twenty minutes. The patient complained a good deal of the hot water and the cautery. At 10:35 the patient became nauseated and vomited. At the same time the pulse became rapid, weak, and irregular. It varied from 100 to 160 beats during the next two hours, on one occasion even going up to 180, yet there was no syncope or other toxic symptom except extreme restlessness. The last part of the operation was very painful to the patient. The pulse rate gradually declined to 100 at 6 P.M. and she became much quieter, passed a very good night, and felt perfectly well in the morning.

CASE XVII.—M. M——. Endometritis; lacerated perineum. At 10:06 A.M., November 30th, we injected gr. $\frac{1}{3}$ cocaine; anæsthesia was complete in four minutes. The curettage and perineorrhaphy were complete by 10:50. The patient was at first rather nervous, but experienced no pain. Complete anæsthesia lasted until 11:10 A.M. No disagreeable symptoms of any kind developed.

CASE XVIII.—E. B——. Lacerated perineum. Cocaine gr. $\frac{1}{3}$ was injected at 9:49 A.M. Anæsthesia began in two minutes and was complete in five minutes. It lasted over two hours. Outside of vomiting there were no disagreeable symptoms. The perineorrhaphy was concluded without pain at 10:40. At 11:20 the patient noticed a numbness in the lower extremities and a stinging at the site of the operation. At 1:30 P.M. she was perspiring freely and complained of some headache. She slept well all night.

CASE XIX.—J. L——. Chronic endometritis; relaxed perineum. Cocaine gr. $\frac{1}{3}$ was injected at 10:17 A.M., December 3d. The patient was of a very nervous temperament; at times she complained of being uncomfortable and said she could "feel the curetting," but nevertheless remained perfectly quiet. Anæsthesia was established five minutes after the injection. The patient could not feel the pricking of a pin in the lower extremities up to 11:15 A.M. After the curettage a perineorrhaphy was done. The process of denudation was not painful, but when the perineal sutures

were inserted the patient complained. Normal sensation, however, did not return until 12 M., after the patient had returned to bed. No disagreeable symptoms whatever were noted.

Case XX.—R. T——. Endometritis; retroversion; lacerated perineum. Cocaine gr. $\frac{1}{3}$ was injected at 9:26 A.M., December 4th; complete anæsthesia resulting in four minutes. The uterus was first curetted, then the bladder was separated from the uterus, the anterior cul-de-sac opened, and the uterus brought forward into normal position. The fundus was then sutured high on the vesical peritoneum and the vaginal incision closed. A perineorrhaphy was next done, and as the last sutures were inserted the patient complained of some pain. The operation lasted one hour and ten minutes. The patient did not recover from the anæsthetic until half an hour after completion of the operation.

Case XXI.—G. W——. Endometritis; lacerated cervix; lacerated perineum; recto-vaginal fistula. Cocaine gr. $\frac{1}{3}$ was injected at 10:23 A.M., December 11th. Anæsthesia resulted in four minutes. Slight astonishing. In from two to four minutes, as a rule, all sense of pain was gone. Eleven minutes was the longest we ever had to wait. In the gynæcological cases it was complete before the woman could be put in position for the operation. It usually extended up to a line drawn between the nipples. With smaller doses of cocaine, however, it did not, as a rule, go higher than the umbilicus. Shortly after the injection, uterine contractions became absolutely painless, in fact, were, as a rule, not even noted by the patient, but were felt only by the hand of the obstetrician placed on the abdomen. This total anæsthesia lasted for one to two hours and was followed by a shorter period of about a half an hour in which, while not painful or only slightly so, the patient again noticed the contractions. There was frequently a hypalgesia after the narcosis had disappeared.

The influence of the cocaine injection upon the nervous centres was various in its manifestations. Thus, in nine of the twenty-one cases the knee jerk was increased, in one case it was lost, and in the others it was unchanged. Dilatation of the pupils appeared in

vomiting occurred. After the curettage, a unilateral laceration of the cervix was repaired, then the perineum and fistula were denuded and sutured. Throughout that operation, which lasted one hour and twenty minutes, the patient remained entirely composed asked questions of the nurse, and did not even feel uncomfortable. She had full control of her bowels all the time, hence the field of operation was never soiled. At 12:10 the sensation of pain returned and the patient complained of burning at the site of the operation.

It will be observed from a study of these cases that the duration of the anæsthesia was dependent, as a rule, on the amount of cocaine injected. Thus gr. $\frac{1}{5}$ cocaine produced on an average an anæsthesia of one hour twenty-one minutes; gr. $\frac{1}{4}$, anæsthesia of one hour twenty-six minutes, and gr. $\frac{1}{3}$, anæsthesia of one hour fifty-nine minutes. It depended even more on whether the cocaine was boiled or not. When it was boiled the anæsthesia lasted thirty-five minutes, whereas under the pasteurization the duration was on an average one hour fifty minutes. The shortest duration of anæsthesia was in the first case, twelve minutes and the longest was four hours three minutes. As a rule, the anæsthesia was sufficiently prolonged to accomplish its purpose. In nine cases there was some pain, and in three of these cases it was severe enough to require a few inhalations of chloroform. Our later cases were more successful. In only one of the last ten did the operation or labor outlast the anæsthesia. The rapidity with which the anæsthesia formed was five cases. Three times the heat-and-cold sense was absent. As a rule, it was not at all impaired, however, and in one case in which the cautery was used it brought forth an expression of pain, possibly by association of ideas, as the cutting of a knife at the same time produced no such effect. Tactile sense was fully retained. The patient could tell at any time whether a pointed, blunt, flat, or curved instrument was being used.

Only two of our patients, Case VIII. and Case XVI., developed symptoms that were in any sense serious. In neither case did the patient's life seem to be endangered. Usually the patient's condition was unchanged and in four cases there was even some improvement in the pulse.

The most constant toxic symptom was the vomiting. It appeared in seventy per cent. of our cases, coming on within ten minutes of the injection. It was accompanied by considerable nausea, but lasted only a few minutes. It is worthy of note that, whereas twelve out of fourteen obstetrical cases were characterized by vomiting, it appeared in only three out of seven gynæcological cases. This might be explained by the fact that vomiting is a frequent concomitant of a normal labor. Headache we did not find so frequent a symptom as previous reports had led us to believe. In but three cases did it appear, and was then neither severe nor lasting. Twelve hours after injection a rise of temperature to 101°–102° was observed in most of the cases, but this was also found to be more frequent in the obstetrical ones. It was noted in only

one of the seven operative cases. Of the minor symptoms the most prominent were restlessness, trembling, and perspiration. In all the cases, after twenty-four hours had elapsed the patient was free from any manifestations of the cocaine. No sequelæ have been noted thus far.

A special table has been prepared to show the effect of the injection on the progress of labor. The injection was usually not given until the cervix was completely dilated and in primiparæ was often delayed until the head was on the perineum. Hence, the first stage of labor was not affected. After the injection, in seventy per cent. of the cases, the pains were, as a rule, neither as prolonged nor as powerful as before. Twice the pains continued as strong as before, and the other two times the cocaine seemed to stimulate the uterus to expel its contents. In frequency the contractions were not much affected, being more often increased in number than otherwise. In like manner the abdominal muscles were not brought into play so well as before the injection. Many of the primiparæ not knowing how to bear down, and not stimulated thereto by the pain itself, let the contractions pass unaided in spite of the appeals of the accoucheur. It is not surprising, therefore, that the average duration of the second stage of labor in primiparæ was three hours twelve minutes. In several cases the head remained on perineum for four hours. The forceps was applied only when the condition of the mother or the child absolutely demanded it. Yet this was necessary in five out of eleven primiparæ. In two of these, however, the blame may not be attributed to the spinal anæsthesia; in one case asphyxia of the child necessitated the application, and in the other one the presentation was a persistent occipito-posterior. In the other three the forceps was applied because of delayed labor and it is hard to find any special reason for this delay except the cocaine injection.

In five cases the cocaine seemed to have a toxic effect upon the child. A pulse that had been 140 would drop to 90–100 shortly after the injection and after remaining so about ten minutes would again return to its normal rate. Three times the child was somewhat asphyxiated when born. One child died, but in this case there were symptoms of weakness before the injection was made. There was no case of post-partum hemorrhage in our series. In fact, the bleeding was unusually small in amount. The average duration of the third stage of labor was only about ten minutes. Of the eight perineal lacerations only two were of any extent. Even so, this is a rather large percentage. The perineal body did not seem to relax so well as under chloroform.

To summarize, then, our results, as far as they go, would tend to support the view that spinal anæsthesia is not very dangerous, except perhaps to the child in utero. When it produces disagreeable symptoms, they are usually transient. In the labor cases it usually retarded progress. Finally, the anæsthesia it produces is for a fairly definite period of time without affecting consciousnes and with full control of the voluntary muscles.

It only remains to consider in brief the indications. From a study of these cases the use of the lumbar puncture in multiparæ would seem to be less called for than inhalations of chloroform. The results obtained from its use in primiparæ were also not very encouraging, but when good results can be obtained in a few cases the experiments should be continued.

In instrumental deliveries, when urgency is required and the patient is not of a very nervous temperament, the spinal narcosis seems to meet every indication. The delivery would be much facilitated by the patient's aid, which is not obtained under general narcosis, and the dangers of retained placenta and post-partum hemorrhage are lessened.

It is doubtful if the puncture will ever replace general narcosis in abdominal operations. In vaginal cœliotomy and minor gynæcological work it seems to have its greatest field of usefulness and will, we believe, come more in vogue as its merits are more fully observed and understood.

IMPORTANT POINTS IN THE MANAGEMENT AND TREATMENT OF CONSUMPTION.

By CHARLES R. UPSON, M.D.,

WATERBURY, CONN.

Much has been written on the etiology, symptomatology, prognosis, and treatment of pulmonary tuberculosis, but comparatively little has been said of the physician's responsibility in the management of these cases.

In no other disease does the physician undertake a greater responsibility than in the management of a case of tuberculosis. His errors—both of commission and omission—may not only prejudice the results of his treatment but also jeopardize the health and happiness of others.

The physician who is the most successful in the treatment of consumption is one who can and will give plenty of time to the examination and supervision of his patient; who makes an early diagnosis and at once advises him—or, in the case of an extremely nervous person, some relative or friend—of his conditon; who can inspire in the patient a degree of confidence that will prompt him faithfully to carry out the physician's directions; who is not wedded to routine but can individualize symptoms and treat them accordingly—for there is no "royal road" to the cure of consumption.

If the general practitioner—for he is the one most frequently consulted by the consumptive in the early stage of the disease—would exercise the same care in the examination and management of his patient that he would give to, say, a case of pneumonia, the death rate from this disease would be materially lessened.

A few words regarding heredity as causative of consumption. While I am not prepared to say that consumption is never inherited, I am nevertheless firmly of the opinion that heredity is entitled to but little consideration as a factor in the etiology of the disease.

A person may inherit a low vitality, which renders him peculiarly susceptible to morbific influences, but he does not inherit the disease itself. While it is true that several members of a family may contract consumption, its causation can usually be traced to infection.

I have in mind a family consisting of a man, his wife, and four children, in which the wife and two of the children died of consumption. Both the father and mother had good personal and family histories, and the individual members of this family were apparently well up to the time that the mother contracted the disease, after nursing a case of acute pulmonary tuberculosis. Previous to this the two older children had left home and they escaped the disease. Seven months after his wife's death the man married again—a woman whose personal and family history was also good and whose health at that time was to all appearance perfect. Within six months of her marriage she showed unmistakable evidence of having contracted the disease. Fortunately for her, the house in which she lived, with all it contained, was destroyed by fire and she, under more favorable home environment, was

restored to health. One taking a superficial view of the history of this family might be led to attribute the causation of the disease in the cases of the two younger children to hereditary transmission rather than to the true exciting cause, infection.

Twenty-five years devoted to the special study and treatment of pulmonary tuberculosis afford to my mind abundant proof of the curability of many cases of the disease. This experience has taught me that the conditions under which a favorable prognosis may be given are as follows: If the disease is localized in one or even in both lungs; if the patient's digestion and assimilation are or can be made good, his sleep is restful, his environment healthful; and if he is possessed of a firm determination to "get well," we may safely give a favorable prognosis. But unfortunately, in many cases, when the consumptive consults a physician he presents a much more unfavorable aggregation of symptoms, among which may be mentioned disseminated tuberculosis; a rapid pulse in the early stage of the disease, which is out of proportion to his pulmonary condition; progressive loss of flesh, even when he has a fair appetite; a constant high temperature; profound anorexia; intemperate habits and a neurotic temperament, which makes him notional, impatient of restraint, and easily influenced to change physicians and localities. In these cases the prognosis is unfavorable.

The peculiar mental condition of the consumptive often prompts him to minimize symptoms and suppress facts in his personal and family history, which, if known, might assist the physician in arriving at a satisfactory diagnosis.

Extreme care and thoroughness should, therefore, be exercised in the examinaton of these cases, if we would be successful in their treatment.

Omitting a description of the physical signs of pulmonary tuberculosis—with which the reader is doubtless familiar—I will briefly call attention to certain other symptoms indicative of the early stage of the disease—as the prominent bright eyes, often with dilated pupils; morning pallor; an afternoon rise of temperature with, in some cases, a subnormal morning temperature; a quickened pulse; more or less shortness of breath on slight exertion; a slight cough on first assuming a recumbent posture, or an early morning cough with little or no expectoration, or both; occasional night sweating, which, however, may be so slight as hardly to attract attention; "nervousness," with disturbed sleep; a feeling of fatigue on arising in the morning, even after a good night's rest, which, however, may pass away within a few hours; a capricious appetite, frequent attacks of intestinal indigestion, and constant or recurring pain in the clavicular and subscapular regions.

While but few cases will present all of the above-mentioned symptoms, the presence of a majority of them in a given case—even in the absence of physical signs—especially if accompanied with a history of blood-spitting should excite suspicion of the existence of a tuberculous condition.

An invaluable aid in the physical examination of the upper portion of the lung in a case of suspected tuberculosis is the method suggested, I think, by Dr. H. P. Loomis, who directs that "the patient's hand be placed on the opposite shoulder"—which draws the scapula forward—when by placing the ear over the uncovered portion of lung we can, if they be present, detect in the "prolonged tubular breathing and fine râles on coughing" early evidence of the disease.

A laryngoscopic examination of the pharyngo-laryngeal regions will frequently aid us in making an early diagnosis in suspected cases. The pharyngeal and laryngeal mucous membrane presents a decidedly pale appearance, with, in some cases, a more or less marked local congestion of the mucous membrane lining the arytenoid region.

The microscopical demonstration of the presence in the sputa of the tubercle bacillus places, of course, the diagnosis of pulmonary tuberculosis beyond doubt.

The most important points in the management of pulmonary tuberculosis may be briefly summarized under the following heads: The patient should occupy a good-sized, well-lighted room with a southern exposure, from which the carpet, draperies, and upholstered furniture should be excluded. The floor should be frequently cleansed with a mop moistened with a five-per-cent. solution of formic aldehyde and the furniture wiped with cloths dampened with the same solution.

Covered sputa cups, containing a small quantity of the formaldehyde solution, should be used by the patient and should be thoroughly cleansed at least three times in the twenty-four hours. Sputa cloths, to be used for the reception of sputa when the patient cannot use his cup, can be cheaply made from cheese cloth, cut into squares about the size of a lady's handkerchief.

After use these cloths should be sprinkled with the above-mentioned formaldehyde solution and placed in a covered vessel until they can be burned. I have adopted the practice of placing in the hands of my consumptive patients a circular—of which the preceding suggestions form a part—calling attention to the cause of the disease, the dangers of infection, and giving plain directions how to avoid the same.

Under general medication may be mentioned, first, what may be called preparatory treatment—consisting of a dose of calomel and soda at 9 P.M., to be followed in the morning by a saline. This measure, cleansing the intestinal tract, is usually well borne and is, in some cases, followed by a reduction of the afternoon temperature. This treatment should be repeated weekly. For the relief of the intestinal indigestion, creosote, combined with hydrastis and some simple bitter, will be found useful; as a tonic-alterative there is nothing better than a combination of strychnine arsenate, arsenic iodide, caffeine, and calcium sulphide. The anorexia will sometimes yield to orexin, even after the failure of other remedies. Cough mixtures are to be avoided, unless urgently called for, in which case codeine phosphate, or heroin, combined with small doses of potassium bichromate, may be used with good effect.

Hæmoptysis is best treated by rest in a reclining position and the use of hypodermic injections of atropine and morphine. If the hemorrhage be severe, bandages are to be applied to the extremities. Fluids should—if used at all—be given in small quantities and cold. To assist nature in the formation of a clot, calcium chloride may be used with good results. The "night sweats" are often relieved by the use of intestinal antiseptics and small doses of atropine. Copper arsenate or the sulphocarbolate of zinc acts well in cases of diarrhœa. For constipation there is nothing better than small doses of the aromatic elixir of cascara sagrada one-half hour before meals.

Essentials are an abundance of fresh air at all hours of the day and night, and good nourishing food; gentle exercise in the open air when the patient's temperature does not exceed 99.5° F., but when above this point we should insist upon rest, either out of doors or in a well-ventilated room; systematic respiratory exercise; daily sponging of the body with tepid or cold water, followed by vigorous friction with a coarse towel, after which from one-half to one ounce of lard is to be well rubbed into the skin.

Some writers on pulmonary tuberculosis advise against the use of intrapulmonary medication. A rather large and favorable experience in the use of

local treatment in these cases justifies my taking exception to such views, as I have demonstrated times without number the exceeding value of properly selected remedies thus applied—the frequent use of a mixture of eucalyptol, pine-needle oil, menthol, and formic aldehyde having proven in my hands the most beneficial. But we are more apt to prescribe too much, rather than too little, medicine in cases of consumption.

In conclusion, I would urge upon the physician the importance of the strictest attention to the hygienic environment of the consumptive patient. The more rigidly we follow the methods adopted in lung sanatoria in the management of these patients the greater will be our success—the constant supervision and control of the patient being the most important factor in the cure of the disease.

Dipsomania and its Treatment by Suggestion.—J. Milne Bramwell lays down the following rules concerning this application of suggestion therapy: (1) The patient must be willing to be cured. Difficulties as to this are more frequently encountered in cases of chronic alcoholism than in dipsomania. (2) Susceptibility to hypnosis is a varying and important factor. Most authorities agree that all, except idiots and those suffering from certain forms of mental disease, can be hypnotized. On the other hand, time and trouble are often requisite and frequently slight hypnosis alone can be induced. (3) In dipsomania one ought to begin treatment at the commencement of a period of quiescence, and aim at preventing, or at all events retarding and weakening, the next attack. (4) The management of the patient during the earlier part of the treatment, before suggestion has taken effect, is important. If possible, he should not be left alone, but always have near him some trustworthy person to whom he can confide his temptations, and turn for aid in overcoming them. (5) The operator must be persevering and not easily discouraged; many patients, who ultimately do well, relapse more than once during treatment. (6) A distaste for alcohol ought to be suggested, as well as the abolition of the craving for it. The patient must be made to understand that he can never look forward to being a moderate drinker, and that the only choice before him lies between total abstinence or the gutter. (7) Even when the craving disappears quickly, the patients ought to be hypnotized regularly for a month. If they can be seen from time to time for the next six months, so much the better and safer. (8) The object of the treatment is not only to cure the diseased craving, but also to strengthen the will of the patient and help him to combat the temptations of social life.—*Medical Press and Circular*, November 7, 1900.

Is Widal's Reaction Reliable?—William Murrell reports several cases in which Widal's reaction was obtained respectively in obstructive jaundice due to an impacted gall stone, cerebral suppuration, abdominal tumor, and a fever probably due to bronchial catarrh. Cases such as these, he says, tend to shake one's faith in the infallibility of Widal's reaction as a test for enteric fever. Van Oordt and Kasel and Mann, under what may be fairly called test conditions, have obtained the reaction, the former in a case of malignant endocarditis, and the latter in two cases of pneumonia. It is stated, apparently on the authority of Malvoz, that certain bodies, such as safranin and vesuvin, have the power of agglutinating the typhoid bacillus, and that when abnormal reactions are obtained some analogous substance may be present in the blood. If the agglutination can be obtained when they occur, and in a certain percentage of cases of ulcerative endocarditis, pneumonia, jaundice, and even floating kidney, it must be admitted that Widal's reaction is not immaculate, and that as yet the clinical physician is not entirely superseded by the bacteriologist.—*The Medical Press*, November 21, 1900.

The Early Diagnosis of Fluid in the Abdominal Cavity.—L. Landau suggests a sign which he has found of value in determining the presence of small quantities of free fluid in the abdomen. In the early stages of ascites percussion and palpation are useless and exploratory puncture is hazardous, so that the author's sign should prove a useful addition to our diagnostic procedures. It consists in the fact that when the pelvis is filled with a small quantity of fluid, in practising bimanual palpation the examining hands find difficulty in approximating themselves to each other laterally, while the usually somewhat low-lying uterus gives the impression as if it floated on an air or water cushion. If now the pelvis be raised and the examination repeated these conditions disappear owing to the escape of the fluid into the upper portions of the cavity, and palpation gives the customary sensations.—*Centralblatt für Gynäkologie*, November 10, 1900.

Studies in Astereognosis.—F. X. Dercum claims to have been the first to use the terms stereognosis and astereognosis, the former meaning the faculty of being able to recognize foreign bodies, and the latter the absence or loss of this faculty. His conclusions from the observation of cases are that the loss or impairment of the spacing sense is the most important factor in determining astereognosis, but not the only one. Next in importance to the spacing-sense appears to be the knowledge of the position of the fingers and ataxia of movement. The mere preservation of the ability to perceive tactile impressions and the preservation of the pressure, temperature, and pain senses is insufficient to prevent stereognostic loss. It is known that astereognosis may at times be cortical and at times peripheral, but at present we do not know that there are any means by which the symptom can be made of differential value. It is not, however, impossible that it may be so employed.—*The Journal of Nervous and Mental Disease*, November, 1900.

The Prognosis of Various Types of Albuminuria.—Talbot Jones discusses the organic and the functional groups of albuminuria. The prognosis of the various forms of functional trouble he gives as follows: Cyclic albuminuria: the trend of opinion is toward regarding it as a manifestation of slight nephritis which may gradually pass into Bright's. The prognosis is therefore not absolutely unfavorable. Physiological albuminuria the author does not believe to exist. Infective and toxic albuminuria: the prognosis is that of the original disease. Gout and lead poisoning: the prognosis is bad, since it has been shown, both clinically and experimentally, that the albuminuria of these conditions is accompanied by such organic disease as is found in the granular kidney of Bright's disease. "Minimum" albuminuria of the French has an uncertain prognosis, because it often constitutes the first stage of Bright's disease. Anæmia: the albuminuria in this condition is benign. Nervous disorders sometimes cause temporary albuminuria. The prognosis is that of the producing disease. Dyspepsia, highly nitrogenous food, some dermatoses, the blowing of wind instruments by the young, burns, cold bathing, prolonged mental effort, inhalation of sewer gas, and excessive muscular exertion may all cause albuminuria. The frequent repetition of the last-named form can scarcely fail to terminate in chronic nephritis sooner or later.—*The Medical Examiner and Practitioner*, November, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

INFLUENZA.

THIS troublesome and serious disease is once again present in pandemic form in the United States. From accounts received from all parts of the country it would appear that an almost universal outbreak of influenza has occurred. The subject of influenza has within the past twenty years been discussed and investigated from every conceivable standpoint, but so various are its forms that it still presents many mystifying features, and a much more complete elucidation is required before the statement can be truthfully made that all the links in the chain of evidence have been collected and tabulated.

Regarding the etiology of the grippe, authorities are agreed that it is of microbic origin, and the opinion prevails that to Pfeiffer belongs the honor of discovering and isolating the microbe. This is well set forth in Finkler's masterly monograph on the question published in the "Twentieth Century Practice of Medicine." Dr. Goodhart, however, writing in Allbutt's "System of Medicine," with customary British conservatism, while conceding that the malady is due to germs, and admitting that Pfeiffer was the first to distinguish and describe the minute microbe clearly, believes that much has yet to be learned concerning the etiology and pathology of influenza. Finkler says that he is of the opinion that there exists a pandemic influenza caused by Pfeiffer's bacillus, and also an epidemic endemic influenza of identical nature which develops after the pandemic infection has run its course, being caused by germs left by the latter. The occurrence of various forms of catarrhal fever, which are often called grippe or influenza by physicians and laymen, is something altogether different. Sporadic cases of coryza and bronchial catarrh should never be mistaken for influenza, although the symptoms of influenza may be imitated in an exquisite manner. In a few words the celebrated Bonn professor's advice is that a complaint presenting catarrhal features should not be diagnosed as true influenza until the characteristic microbe has been found. A disease of so protean a nature and of so variable manifestation is even to the skilled physician at times exceedingly difficult to diagnose correctly.

The most distinctive mark of typical severe influenza is its remarkably sudden onset, the only disease which resembles it in this respect being Asiatic cholera. At the same time on occasions its period of incubation varies largely, not only in individuals but in different epidemics. Nevertheless, an unheralded attack termed by the Germans "Blitz-Katarrh" (lightning catarrh) is by far the most frequent warning of the presence of the influenza bacillus in the human subject.

Other symptoms are: headache of a particularly racking type, frontal or orbital, often the precursor of delirium; acute aches and pains in the back, not unlike those which are the forerunners of variola. The condition of the tongue is peculiar to the disease. According to Goodhart, it is generally tremulous, swollen, soft, and coated with a thick, creamy, dirty fur, accompanied usually by a particularly offensive smell of the breath. The sweat, also, has an odor peculiar to this disease alone. Sometimes the coryzal symptoms are severe to a degree, and sometimes a dry and hard cough is an accompaniment. The temperature varies very considerably, occasionally running to a high point, but often rising to no appreciable extent. Rigors and drenching sweats are a not uncommon feature in the course of the complaint. Goodhart rightly lays especial stress upon the value in diagnosis of an extensive diffusion over the bases of the lungs of characteristic sharp, sticky râles. Although the claim may be advanced with justice that much progress has been made during the preceding eight or ten years so far as a knowledge of the etiology and pathology of influenza is concerned, but little improvement can be shown in our methods of treatment and prophylaxis. No specific for the malady is known, and the majority of physicians the world over appear to have come to the conclusion that each individual case should be treated on its merits, and that therapeutic remedies for influenza, *per se*, have but slight curative effects.

The German committee, which was formed after the epidemic of 1892, after obtaining the opinions of six thousand physicians in that country, stated in a general way that the use of drugs had been overdone in the treatment of influenza, and that a doctor's intelligent advice was of infinitely more benefit than quantities of medicine. Dr. Fürbringer, of the said commiteee, declared that it was more than doubtful whether many patients did not suffer less from influenza than from the "galenical poisoning" induced by self-prescribed medicines. Panic, brought on by the depressing influence of the affection, is responsible for this mode of treatment. The patient who thinks he is "in for an attack," should consult a physician without delay and be guided by reason and clinical experience. Rest in bed, the shunning of drastic agents, and, above all, curbing the desire to leave the sick-room until the seeds of the disease are entirely eliminated from the system, are the only rational procedures. One great precaution to be observed in the treatment of influenza, as indeed in the treatment of all contagious diseases, is the thorough ventilation of the sick-room and of houses in which cases occur. Ill-ventilated buildings are eminently favorable to the spread of the malady, and any manner of living which tends to lower the vital powers will naturally render a person more

prone to infection. But while influenza is a self-limited disease, and mild and uncomplicated cases may safely be left to the resources of nature, it is unfortunately true that the disease has to a greater extent than any other the faculty of attacking some weak spot in a person's armor; hence complications are numerous, and in virtue of the complications and sequelæ, often proves disastrous. The most common complications and sequelæ, it is superfluous to remark, are respiratory affections, of which pneumonia is the most fatal. A point to which attention has been frequently drawn within recent times, is the baneful effect that influenza exerts upon the nervous system; this, judging from the records of ancient epidemics, does not appear to have formerly been a prominent characteristic. In fact, taking it all in all, influenza as it presents now, is perhaps the most insidious and dangerous disease which attacks civilized races. There are no known means of effectually guarding against its onslaughts. The best preventive measures are undoubtedly to strengthen and brace up the system by living an active, healthy life, and by avoiding as far as is possible the badly ventilated, overheated rooms which are so prevalent throughout America. An editorial in the Medical Record, written at the time of the last epidemic in this country, emphasized the fact that the inhabitants of the United States appeared to be in an uncommon degree susceptible to the morbific influence of grippe, and the surmise was made that this proneness to contract the disease might be in part due to the highly-strung nervous organization of the native-born population. It may now be added that another, and possibly more potent cause is to be found in the pernicious habit of keeping the temperature of public offices and of houses unnecessarily high.

ORIGIN AND SPREAD OF TYPHOID FEVER IN THE UNITED STATES ARMY DURING THE SPANISH WAR.

Despite the experience so dearly earned in every war of any length which has been waged since written records were first kept, the means of preventing the occurrence of typhoid fever or of even staying its spread would seem to be almost as ineffective as in the campaigns of Napoleon. This conclusion is forced upon us by the devastation caused among American troops by this disease during the Spanish-American war, and further emphasized by its prevalence and deadliness in the British South African army. There has recently been published a report dealing with the matter by Dr. Walter Reed, Major and Surgeon, U. S. A., Dr. Victor C. Vaughn, Major and Division Surgeon, U. S. V., and Dr. Edward O. Shakespeare, Major and Brigade Surgeon, U. S. V., which provides some gruesome reading, while at the same time it supplies some valuable suggestions. The following is a portion of the conclusions reached: (1) During the Spanish war of 1898 every regiment constituting the first, second, third, fourth, fifth, and seventh army corps developed typhoid fever; (2) more than ninety per cent. of the volunteer regiments developed typhoid fever within eight weeks after going into camp; (3) typhoid fever developed also in certain of the regular regiments within three to five weeks after going into camp, (4) typhoid fever became epidemic in camps located in the Northern as well as in those located in the Southern States; (5) typhoid fever is so widely distributed in this country that one or more cases are likely to appear in any regiment within eight weeks after assembly; (6) typhoid fever usually appears in military expeditions within eight weeks after assembly. These are all hard, undeniable facts. As to the origin of typhoid fever, the three investigators declare: (1) The miasmatic theory of the origin of typhoid fever is not supported by our investigations; (2) the pathogenic theory of the origin of typhoid fever is not supported by our investigations; (3) our investigations confirm the doctrine of the specific origin of typhoid fever; (4) with typhoid fever so widely disseminated as it is in this country, the chances are that if a regiment of thirteen hundred men should be assembled in any section and kept in a camp, the sanitary conditions of which were perfect, one or more cases of typhoid fever would develop; (5) typhoid fever is disseminated by the transference of the excretions of an infected individual to the alimentary canals of others; (6) typhoid fever is more likely to become epidemic in camps than in civil life, because of the greater difficulty of disposing of the excretions from the human body; (7) infected water was not an important factor in the spread of typhoid fever in the national encampment in 1898; (8) flies undoubtedly served as carriers of infection; (9) it is probable that the infection can be disseminated to some extent through the air in the form of dust. The foregoing conclusion as to the modes of infection are more or less in accord with the views of other authorities both in this country and in Europe. Special stress is, we think, rightly laid on flies as a potent means of spreading typhoid fever. Dust, too, is probably more often a factor in disseminating the disease than is commonly supposed. This theory would appear to have received a certain amount of confirmation in South Africa, than which no part of the world is more subject to dust storms. To what extent the water supply of the camps of the United States troops was responsible for the prevalence of typhoid, it is undoubtedly very difficult to state with much degree of accuracy. The writers of the report seem inclined to think that in the camps in question contaminated water played an inconspicuous part as a carrier of infection. True as this may have been in the case of our soldiers and volunteers in 1898, there can be little doubt that, as a rule, polluted water has been to blame for originating and spreading typhoid fever more than any other one cause in almost all the great epidemics which have ever occurred. The suggestions advanced in the report as to the preventive and remedial measures to be adopted when typhoid fever has broken out in camps, provide the most valuable reading. It is pointed out that a command badly infected with typhoid fever does not lose the infection by simply changing location, because when such a command makes another encampment, it carries the specific agents of the disease in the bodies of the men, in their clothing, bedding, and tentage; there-

fore, a thorough disinfection of these impedimenta is necessary. The excellent advice is also given that the soldier's bed should be raised from the ground, and that overcrowding should be strictly avoided. The report draws attention to the need of careful diagnosis in cases resembling malaria among soldiers. The statement is made that malaria was not a prevalent disease among the troops that remained in the United States, and that many short or abortive attacks of typhoid fever were diagnosed as some form of malarial fever. In connection with this fact, it is suggested that to each division of an army a hospital should be furnished, with facilities for scientific diagnosis equivalent to those possessed by all first-class hospitals. Lastly, the compilers of the report declare that the belief that errors of diet with consequent gastric and intestinal catarrh induce typhoid fever is not supported by these investigations, nor is the belief that simple gastro-intestinal disturbances predispose to the disease.

MEDICAL EVIDENCE.

Every one is agreed that the manner in which medical evidence is given, both in civil and in criminal actions, is open to severe and just criticism in various particulars. The question of the physician as an expert witness has been fully and freely discussed by his brother practitioners, by medical journals, by the members of the legal fraternity, and the verdict has been given that under the existing system he is a failure.

Many are the schemes which have been evolved by ingenious thinkers to remedy the present discordant state of affairs, but so intricate is the problem that nothing really practical has as yet been accomplished.

Dr. R. L. Pritchard gave a clear exposition of the subject before the Society of Medical Jurisprudence on November 12th, 1900, in which he traversed the well-worn old paths as well as broke some fresh ground. A point to which he draws attention is one that, although it must have often occurred to all interested in the matter, has been seldom directly referred to. The different ideas regarding medical evidence entertained by the medical and legal professions are well presented.

The lawyer looks upon medical evidence as a very unsatisfactory kind of testimony, as the evidence of his medical witness is scarcely ever more positive than opposing testimony on the other side. To the legal profession it is a matter of doubt whether these differences are the result of the uncertainty of medicine as a science or the different refraction of the medical witness's mind when testifying for the plaintiff or for the defendant. On the other hand, the medical profession admits the apparent inconsistencies of medical evidence, but attributes them to legal assumption in endeavoring to comprehend, harmonize, and explain medical matters after a limited study of a particular case.

Dr. Pritchard regards the subject from the standpoint of both professions, and although not positively pointing a way out of an increasingly unbearable situation, reviews the entire matter lucidly. The method always recommended by the Medical Record, of creating a commission of independent and impartial experts, does not find favor in the eyes of Dr. Pritchard, who argues that such a mode of procuring experts would limit litigants in their selection of witnesses. And, further, if the expert witnesses were appointed by the court, the unsuccessful party would feel aggrieved that an expert, in whose ability or knowledge of the merits of the case he had no confidence, had decided the extent of his injuries. Dr. Pritchard, in short, would have no system which would interfere with the litigant in proving his case as best he can.

He is of the opinion that the defects in the plaintiff's medical evidence is his reliance for advice and testimony upon the attending physician, and contends that the duties of witness and medical adviser ought not be expected from the same person without subjecting one to the other.

Commenting upon the defects of medical evidence on the part of the defence, the writer thinks it is owing to its experts too often testifying without a sufficient knowledge of the plaintiff's injuries, and that what the defence requires is to know before the trial as much of the plaintiff's injuries as the plaintiff intends to prove. Dr. Pritchard ends an able, if not altogether convincing, address as follows: "The existing practice of medical evidence can be submitted to the courts with the number and extent of opposing opinions not greater than the reversals and dissenting opinions of appellate courts. And where expert opinions would differ an intelligent jury would have no difficulty in finding where the weight of opinion preponderates, as juries have always to do wherever there is a conflict of evidence.

"The value of medical evidence, where it is submitted on facts such as a lay jury can understand and appreciate, is greater than that of other oral evidence. Medical evidence is not the testimony given by the senses, which are greatly liable to error, but it is testimony of scientific reason which, when made clear, carries conviction."

The reasons adduced against the creation of a board of experts are weighty, but not by any means conclusively so. Such a system would appear to be preferable to the present one, if only because the witnesses would be impartial and independent. The medical profession is assuredly in the bulk honest and honorable, but when, by tendering certain testimony, one's own patient and one's own pocket are likely to benefit, one is unconsciously inclined to be somewhat biassed. The institution of a commission of medical men who had no pecuniary interest whatever in a case, would at least remove temptation from the path of the expert witness, and the evidence would probably be quite as much to the point and as comprehensible to the jury as it is now. There have been several trials in which men in the vanguard of the medical profession have testified in direct opposition to each other. No perfect method of procuring medical expert evidence can, in the nature of things, be hoped for; but, at any rate, reforms might be introduced with advantage to all concerned.

PROPOSED HOSPITAL FOR THE SPECIAL TREATMENT OF ACUTE NERVOUS AND MENTAL DISEASES IN THE CITY OF NEW YORK.

The recent disclosures in Bellevue have attracted attention in all parts of the country to the treatment of the indigent insane. It is to be sincerely hoped—and, indeed, it may be asserted with some degree of confidence—that the state of affairs prevailing in the aforesaid hospital has been exaggerated and that its condition is not quite so black as has been painted. But that there is something entirely wrong in the methods of management in the New York City hospitals must be admitted by every disinterested citizen, and any workable plan that would tend to place these institutions on a satisfactory footing will certainly be hailed with gratitude by all sorts and conditions of men. The treatment of the poor insane in some respects has been for long in certain portions of the United States a blot on the intelligence and humanity of the inhabitants of so rich a land. That an individual has the misfortune to have no money and to lose his wits, should be no reason for treating him more or less as a criminal. The whole question teems with difficulties, and it cannot be reasonably anticipated that an ideal method will be evolved forthwith. Nevertheless, an earnest and serious attempt to better the state of the indigent insane is at least a healthy sign that thoughtful men are becoming alive to their responsibilities and is in itself an augury of progress. Dr. Charles Henry Brown, managing editor of *The Journal of Nervous and Mental Disease*, has recently drafted a bill having this object in view. The bill provides for the establishment within the city and county of New York of a hospital to be known as the "Hospital for the Treatment of Acute Nervous and Mental Diseases." Such hospital is to be under the control and management a board of twelve managers, six of whom shall be regularly licensed practising physicians, and six of whom shall be citizens of the city and county of New York. Such managers are to be appointed by the mayor of the city of New York. The president of the health department and the mayor of the city of New York and the president of the State commission in lunacy are to be ex-officio members of such board of managers.

The most important clause of the bill is section 9, dealing with the admission of patients, which provides that all persons suffering from acute nervous and mental disease, who are residents of the city of New York, may be received at such hospital before their final commitment to a State hospital or other institution according to law, and detained therein for a term of not more than ten days.

The magistrates, or other authorities of the city of New York, may commit to such hospital all persons who appear to be nervously or mentally deranged until such time as their normal condition may be ascertained. Cases of alcoholism, narcomania, or habit neurosis may be committed for a term of ten days, unless in the opinion of the superintendent a longer period is necessary for the health and treatment of the patient and for the safety of the community, under which circumstances an order of a judge in court may be procured, extending such time to a period of thirty days. A person who has been declared insane by duly qualified medical examiners, pursuant to the provisions of the insanity law, may be committed to such hospital by the judge or justice before whom the application for his commitment to an institution for the insane was made, for the purpose of treatment and more minute examination. Such commitment shall not be for a longer period than thirty days, unless otherwise specially ordered by such justice or judge. Convalescent insane may be transferred to such hospital by the authorities of State hospitals and other institutions for the insane, for the purpose of further treatment and surveillance.

The provisions of this bill are to the point, and, if carried into effect, should supply the remedy for many of the evils of the existing system. Especially would it check the power of the policeman and preclude the committal of an innocent person to the prison cell and the consequent criminal stigma attaching thereto. A man or woman has assuredly the right to be judged as to the state of his or her health by an expert and not left to the ignorant, but perhaps well-meaning, tender mercies of the officers of the law.

It is to be presumed that there would be no suspicion of politics in the management of the hospital advocated by Dr. Brown and that the nursing staff would be carefully selected. There is only one feature in connection with the proposal which might, we think, be improved upon. A hospital for the care of insane poor is a matter closely affecting the State, and it would be unfair to the rate payers of New York City that they should be saddled with the entire cost of the construction and maintenance of an institution of that nature.

INVENTION AND EVOLUTION OF MIDWIFERY FORCEPS.

Dr. A. R. Simpson, professor of midwifery and diseases of women at Edinburgh University, writes to the *Scottish Medical and Surgical Journal* "On the Origin and Progress of Artificial Means of Delivery." To the great surgeon Ambrose Paré, toward the close of the sixteenth century, must be accorded the honor of laying the foundation stone of modern midwifery. Paré revived and recommended in his surgical writings the operation of turning as a method of delivery in difficult and dangerous cases, and his pupil Guillemeau still further popularized the procedure in his special work on midwifery. Jean Palfyn, anatomist and surgeon to the city of Ghent, has the merit of having first offered to the profession a rudimentary pair of safe forceps. This was in the year 1720. For more than a century, however, before this date forceps had been in use, but their employment had been restricted to the hands of a very remarkable family which furnished physicians to the English kings, James I., Charles I., Charles II., James II., and William, and to Queen Anne. Huguenot refugees, and by name Chamberlen, this line of medical men flour-

ished exceedingly by reason of their exceptional skill in obstetrical practice. The secret of their success was jealously guarded and handed as a legacy of rare value from father to son through many generations. In 1672 Dr. Hugh, of that ilk, published a translation of Mauriceau's "Midwifery," and in the preface referred somewhat obscurely to midwifery forceps, but although the cause of the Chamberlens' good fortune in bringing infants into the world had been to some extent disclosed, the mystery was not wholly revealed until 1813, when in Dr. Peter Chamberlen's old mansion a chest was discovered, the obstetrical contents of which were deposited among the archives of the Medico-Chirurgical Society, London, where they may be now inspected. Among these treasures the most important are four pairs of efficient midwifery forceps. Dr. Simpson gives as his opinion that the man who did most to popularize its employment and put into the hands of his professional brethren the instrument that gave them the command of the delivery-room, was the Scotchman Smellie, the friend of a still greater Scotch physician, the immortal Tobias Smollett. In the mean time Levret, a Frenchman, had been proceeding along the same path with equally favorable results; but, unfortunately for his reputation, he had not, like Smellie, his Boswell. With regard to the construction of the implements themselves, it is stated that they consisted of two blades, which in the earlier descriptive accounts are termed bows or claws. The blades, the most important parts of the instrument, curved toward one another, each blade being furnished with a handle for purposes of manipulation. The Chamberlen forceps is sometimes spoken of as tongs—by Smellie, among others—and no name could more accurately describe it. Dr. Simpson proceeds to trace further the evolution of the forceps to its present advanced stage, and says: "The forceps that emerged from their obscurity in the beginning of the eighteenth century have undergone two important changes. The lock introduced by Smellie has almost completely replaced the joint of the Chamberlen forceps in British practice, though that has been retained in modified forms in French forceps; while in Germany the Brunninghausen lock is preferred. But whatever minor variations there were in the blades, handles, or lock, the primitive forceps had only the one curve for the adaptation of the blades around the fœtal head which is found in the Chamberlen forceps. Viewed from the side, all these single-curved forceps are straight from the tip of the blades to the handle ends. Levret, of Paris, was first to introduce the pelvic curve, and in January, 1747, presented to the Royal Academy of Surgeons of Paris a new curved forceps contrived for disengaging the fœtal head impacted in the pelvis and arrested at the brim, and in 1757 gave a long description and discussion of its value. Dr. Robert Johnson, a pupil of Smellie, in 1769 invented forceps with what is known as the inverted or perineal curve. It was, nevertheless, not until after anæsthesia began to give the obstetrician greater freedom in the use of instruments that the full value of the long double-curved forceps came to be more fully recognized, and with the more frequent use there grew up a clearer idea of its imperfections as a tractor. Then came the Tarnier axis-traction forceps, which almost wholly solved the question, and in 1880 Simpson himself advocated the employment of forceps constructed on Tarnier's principle, but jointed to the best type of British forceps with, he declares, most satisfactory results. To French surgeons, therefore, belongs the greatest meed of praise both for the invention and perfecting of the midwifery forceps." Dr. Simpson concludes what may without exaggeration be called a fascinating article with a brief discussion of the frequency of forceps cases, and remarks: "How frequently forceps are to be used in practice might be dwelt upon at much length and in the end the question would be determined by the personal equation. Excess of interference is at all times contraindicated, but it is easy to understand that the man who has become familiar with the manipulation of an instrument that he knows to be safe in its application to mother and child, will feel justified in using it to save his own time as well as his patient's suffering, in a case where another man would for a longer time wait and watch the natural efforts. . . . Even this noblest of instruments may be abused, and as we carry it in our obstetric bag, we may do well to say to ourselves what Gideon Gray in Scott's tale, the village surgeon, said to the impatient father of Xilias de Monçada's child, 'Nature must not be hurried and she avenges herself of any attempt to do so.' The best effects of the forceps are secured when we use them, not as a substitute for the efforts of nature, but as an aid when these are like to fail." Dr. Simpson has put together an instructive description of the subject which he knows so intimately—perhaps he has viewed it rather too exclusively from a continental and British standpoint. But this will in no way detract from the real worth of his recorded opinion in the estimation of American readers.

News of the Week.

The Pan-American Medical Congress.—It has been definitely determined that the congress will open on Monday, February 4th. The section meetings will be held in the morning of that and the three succeeding days. The first general session, formally opening the congress, will take place on the evening of February 4th at the Tacan Theatre. The second general session will be on Wednesday evening, and the third, the closing, session on the following evening. On Tuesday evening there will be an entertainment given to the delegates and their ladies by the city council of Havana. Governor-General Wood will give a reception to the delegates, probably on the day before the opening of the congress. In addition to the entertainments already mentioned in a previous notice, there will be an excursion to Rosario, the plantation of Señor Ramon Palayo, and to that of Señor Pessant across the bay from Havana. There will also be an excursion to Matanzas to visit the Caves of Bellamar and the beautiful Yúmuri valley. Those who intend to read papers but who have not yet sent in their titles are requested to send them not only to Dr. T. V. Coronado.

105 Prado, Havana, but also to Dr. Ramon Guitéras, 75 West Fifty-fifth Street, New York City. It is also requested of those who purpose to attend the congress that they send their names to Dr. Guitéras. It is estimated that there will be present about fifteen hundred members of the congress, of whom between three and four hundred will be from this country, two hundred from Mexico, five hundred from the Island of Cuba, and four hundred from the South American republics.

Philadelphia Medical Club.—At the annual meeting held January 11th, the following officers were elected for the ensuing year: *President*, Dr. E. L. Duer; *Vice-Presidents*, Dr. John B. Deaver, Dr. Philip Marvel, of Atlantic City; *Secretary*, Dr. Guy Hinsdale; *Treasurer*, Dr. F. S. Pearce; *Member of the Board of Governors*, Dr. James M. Anders; *Executive Committee*, Dr. T. C. Fulton, Dr. James Van Buskirk, Dr. L. Webster Fox, Dr. Ernest Laplace, and Dr. G. G. Davis.

The Practitioners' Society of Orange, N. J.—At the first annual meeting of this society, held on January 5th, officers were elected as follows: *President*, Dr. Edgar Calvin Seibert; *Vice-President*, Dr. J. Minor Maghee; *Secretary and Treasurer*, Dr. Stephen G. Lee; *Executive Committee*, Drs. M. Herbert Simmons, Walter Dodge, and Frank B. Lane. Dr. Edward J. Ill, of Newark, and Dr. Thomas W. Harvey, of Orange, were elected honorary members.

The Library of the New York Academy of Medicine.—According to the report of the committee on the library of the academy, the number of books in the library, November 30, 1900, was 89,000 volumes, including 36,105 duplicates. There were added during the year, not including duplicates, 3,649 volumes. In the circulating department 971 books and 832 journals were issued to 194 readers. Eleven thousand five hundred and twenty readers registered during the year in the reading-room, and probably many others used the library but did not register. The additions to the library annually for the last four years were about 3,500 volumes a year, not counting 1898, when 7,000 volumes from the library of the New York Hospital were given to the academy. Nine hundred and ninety-one journals in many languages are on file. At present there are 13,430 feet of shelving available, of which less than 3,000 are unoccupied, and 600 feet of shelving are needed annually for the natural growth in new books.

Philadelphia Pediatric Society.—At a stated meeting held January 8th, Dr. S. McC. Hamill exhibited "A Case of Severe Anæmia with Leucocytosis in an Infant of Six Months." Drs. J. A. Scott and H. M. Fisher presented "A Case of Leukæmia in an Infant." The child was seventeen months old and the spleen was enlarged and indurated. Dr. E. E. Graham exhibited a specimen of "Malformation of the Bowel," the anus ending in a blind pouch one inch deep and being separated from the blind lower extremity of the large intestine by a distance of fifteen inches. An attempt at restoration of the continuity of the bowel proved unsuccessful. Dr. D. J. Milton Miller exhibited "A Case of Nodding Spasm" in a rachitic child. Dr. William Pepper read a paper entitled "A Study of Sarcoma of the Liver and Suprarenal Capsule, with Report of a Case."

A Crusade against Quacks.—The board of censors of the Medical Society of the County of New York has issued the following circular asking the aid of the profession in this city in its war against unlicensed practitioners: "The medical laws of the State of New York provide that, before one can practise medicine, a certificate of proficiency shall be obtained from the regents of the university of the State, which is given only after a satisfactory examination. The purpose of this law is to protect the people from incompetent practitioners of medicine, and, in so far as the medical profession is concerned, this purpose is accomplished. There are, however, many irregular practitioners who practise in open defiance of this law apparently without molestation. This is an incentive to irregular methods, and can only be to the disadvantage of the community at large. It is the purpose of the Medical Society of the County of New York to begin an active crusade againt these unlicensed and therefore illegal and incompetent practitioners, and we ask the co-operation of the profession and the public generally. Any information concerning unlicensed practitioners will be gratefully received by the board of censors and the counsel of the society, and will be considered confidential when requested. Communications can be addressed to the members of the board of censors or to the counsel. Frank Van Fleet, M.D., chairman, 63 East Seventy-ninth street; Henry S. Stearns, M.D., secretary, 45 West Fifty-eighth street; Wendell C. Phillips, M.D.; Robert Lewis, Jr., M.D.; Louis A. Rodenstein, M.D., Board of Censors of the Medical Society of the County of New York. Counsel—Hill, Sturcke & Andrews, 52 William street."

Pathological Society of Philadelphia.—At a stated meeting held January 10th, Dr. Joseph McFarland exhibited a specimen of "Epithelioma of the Mouth and Skin of a White Cat-fish," and also a specimen of "Thrombosis of all Four Chambers of the Heart." The case from which the second specimen was obtained was remarkable from the fact that during life symptoms indicative of the fatal condition were not observed. Drs. Ida E. Richardson and J. Dutton Steele exhibited a specimen of "Hour-glass Contraction of the Stomach." The patient had during life at one time presented symptoms of gastric ulcer. The stomach was divided into two pouches of almost equal size connected by a short tube of small calibre. Microscopical examination of the tissue from this latter situation disclosed an absence of muscular fibres and a preponderance of fibrous tissue. Drs. F. X. Dercum and W. G. Spiller read a paper entitled "Nerve Fibres in the Pia of the Cord as a Sign of Regeneration of the Cord." The cord exhibiting this peculiarity was obtained from a case of dolorose adiposis and the nerve fibres were found in the pia upon the posterior aspect. There was no indication of any attempt at regeneration in this case. Dr. L. Napoleon Boston read a paper entitled "Cultivation of the Aspergillus

in Urine." Drs. M. P. Ravenel and D. J. McCarthy read a paper entitled "The Rapid Diagnosis of Rabies," which is based upon the demonstration of parenchymatous and interstitial proliferative changes in the capsule of the cells of the intervertebral ganglia. Dr. W. M. L. Coplin read a paper entitled "Branchial Cysts, with the Report of a Case."

Wills Eye Hospital.—Dr. John Welsh Croskey has resigned as surgeon to the Wills Eye Hospital of Philadelphia from January 1st, and Dr. McCluney Radcliffe has been elected to the vacancy.

The Hospital Ship "Maine" has arrived at Southampton from China with 280 sick and wounded soldiers on board. This is probably the last voyage she will make under the auspices of the American Women's Committee.

Berks County (Pa.) Medical Society.—At the annual meeting and banquet held at Reading, on January 8th, the following officers were elected for the ensuing year: *President*, Dr. S. S. Hill; *Recording Secretary*, Dr. James W. Keiser; *Corresponding Secretary*, Dr. S. Banks Taylor; *Treasurer*, Dr. A. S. Raudenbush.

A Definition of Pure Beer.—A bill has been introduced into the New York Legislature by Senator Malby and Assemblyman Burnett, under the provisions of which pure beer, ale, and porter are construed to be those manufactured from pure products by mechanical process, entirely free from the use of liquids or chemicals.

A Gift to a Chicago College.—The *Tribune* states that Dr. John Kost, a physician of Adrian, Mich., who has several times made liberal donations to educational institutions, has given to the College of Medicine and Surgery of Chicago a museum of zoölogical specimens, valued at $150,000. The articles filled five freight cars when prepared for shipment.

Koch's Discoveries in Malaria.—In my previous remarks on the subject, I said, in my haste, that Professor Koch had contributed nothing to our knowledge of malaria. This is an error, as I find in reading Lord Lister's valedictory address to the Royal Society. After pointing out that MacCallum "observed the act of conjugation in the crescentic human form, though he did not see the subsequent development of the vermiculus," Lord Lister goes on to say that "Koch made a further step by observing the vermiculus of Proteosoma in blood from the mosquito's stomach." This achievement seems to constitute the sum and substance of Professor Koch's "discoveries" in regard to malaria.—*The Practitioner.*

The Prevention of Malaria in the Island of Asinara.—Professor Claudio Fermi and Dr. Tonsini, of Sassari, have recently reported the results of experiments in the prophylaxis of malaria made by them in the island of Asinara, off the northwest coast of Sardinia. They succeeded in destroying the Anopheles larvæ by means of petroleum poured into the pools of the island. This was repeated twice a month. The process was begun in June and continued until the end of November. The mosquitos in the air were destroyed inside houses by means of a mixture of powdered pyrethrum, chrysanthemum, valerian, etc., and the zanzolina of Celli and Casagrandi. In the dormitories of prisons, when there was nothing better available, chlorine, generated by treating calcium chloride with sulphuric acid, was employed. Protective nettings were applied to windows. The result was that hardly any Anopheles were found in any dwelling, while Culex pipiens was much scarcer than in former years. Not a single case of primary malaria was observed.—*British Medical Journal.*

Pennsylvania Hospital.—Dr. Henry W. Cattell has resigned as pathologist to the Pennsylvania Hospital.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy for the week ending January 12, 1901. January 4th.—Surgeon F. Anderson ordered home and to wait orders when recruiting duty is completed. January 8th.—Surgeon C. H. T. Lowndes detached from the Naval Academy January 14th and ordered to the *Lancaster*. Surgeon O. Diehl detached from the *Lancaster* and ordered home to await orders. Passed Assistant Surgeon B. R. Ward detached from the naval hospital, Mare Island, Cal., January 17th, and ordered to navy yard, Boston. Assistant Surgeon J. B. Dennis ordered to the Naval Academy, January 14th.

Obituary Notes.—Dr. Lucius J. W. Lee died at his home in Brooklyn, on January 8th, of pneumonia. He was in the sixty-fifth year of his age. Dr. Lee was a grandnephew of the late Dr. S. D. Gross, of Jefferson Medical College, Philadelphia. He was born in Easton, Pa., and received a grammar-school education. During the civil war Dr. Lee served on the medical staff of Douglass Hospital, in Washington, D. C. After the war he entered the University of Pennsylvania, and was graduated in medicine some years later.

Dr. S. D. Beville, of Alexandria, La., was killed on January 7th by Dr. Gremillion. The killing was the outcome of a professional disagreement. Dr. Beville was in attendance on a patient, and called in Dr. Gremillion as consulting physician. They could not agree. Later Dr. Beville was dismissed by the family and Dr. Gremillion employed. This caused ill-feeling, and when the physicians met on the street a fight followed in which Dr. Beville was shot and died almost instantly. He was a graduate of the medical department of the University of Nashville in 1892. Dr. Gremillion is a graduate of the medical department of Tulane University and served on the staff of Charity Hospital in New Orleans.

Dr. William A. M. Mack, mayor of Elizabeth, N. J., died suddenly on January 14th of disease of the heart. He was born at Glen Gardner, N. J., in 1856, and was at one time a telegraph operator. Later he studied medicine and was graduated from the Bellevue Hospital Medical College in 1878. He began practice in Elizabeth and was elected city physician in 1880, holding that office for several years. At the time of his death he was serving his second term as mayor of the city.

Progress of Medical Science.

Medical News, January 12, 1901.

Splenic Anæmia; Anæmia with Enlargement of the Spleen.—Aloysius O. J. Kelly reports a case of this kind. He states that the occurrence of a symptom complex characterized especially by grave and progressive anæmia and enlargement of the spleen, but unassociated with leucocytosis or enlargement of the lympathic glands, has been recognized for a long time. The patient under consideration was a girl aged twenty-two years. Both the sex and the age are points of interest, as many of the cases reported have been males, and many have been over thirty-five years of age. However, considering all the cases reported, the disease seems to occur with almost equal frequency throughout all periods of life. The enlargement of the spleen in the present instance was not as great as many others have reported. The hemorrhage was very interesting and of an unusual source—from the genitals. The dyspnœa, particularly during the last month or six weeks of life, was extreme, especially upon the slightest exertion. Diarrhœa was a marked symptom at the last: there was no obvious cause for the attacks. The fever, as a rule, was very high—usually 103° to 104° F. The blood changes were similar to those in the larger number of reported cases. Medicinal treatment in these cases is most inefficient. As to operation, satisfactory results may be expected in favorable cases. The disease is supposed to last from six months to two or three years. Cases of rapid course are unsuited for operation. But when the course is slower, and the patient in fairly good condition, operation should be carefully considered.

Some Diagnostic Details.—William Edgar Darnall believes that highly developed perceptive qualities, coupled with the habit of observing details most closely, constitute the chief elements which go to make up a fine diagnostician. No detail is too trivial for a physician's observation. The real value of symptoms must be grasped. The writer then calls attention to the various appearances of the eye; the expression and tone of the voice; the different complexions so characteristic of different diseases, *e.g.*, the roseate nose and florid plethora of the gouty, fit subjects for cerebral hemorrhage; the soft, pasty, white skin of the victim of Bright's disease; the peculiar, lifeless white of the uric-acid diathesis; the bluish lip and bronzed appearance of the cachectic complexion of malignant disease. The breathing and position of a patient may be indicative. The bearing, gait, and even the dress of a patient may often give valuable information. Odors are often very significant, as in typhoid fever, grippe, tuberculosis, sepsis, etc. Temperament must be appreciated in order to insure successful treatment as well as accurate diagnosis. Temperament may be grouped under four heads: (1) Nervous. (2) Sanguine. (3) Bilious. (4) Phlegmatic. Physicians may so train themselves that at a glance they can tell from the color of the hair, the texture of the skin, etc., just what allowance should be made for sensitiveness and reactionary power. The results following this careful attention to details will repay the physician for all the pains expended.

Severe Acute Pleurisy, followed by Phlebitis; Death from Embolism.—By Charles Ross Jackson.

On Gonorrhœal Cystitis in the Female.—By F. Bierhoff.

Case of Dextrocardia.—By Homer M. Thomas.

New York Medical Journal, January 12, 1900.

Dyspeptic Asthma.—F. H. Murdoch describes dyspeptic asthma as a state characterized by great shortness of breath on slight exertion, the condition being not paroxysmal but continuous; it occurs in patients suffering from gastro-intestinal diseases, without any abnormal condition of the heart, lungs, or kidneys, sufficient to account for it, and yields readily to treatment directed against the existing dyspepsia. He gives the clinical histories of five patients, three of whom were suffering from achylia gastrica, one from hyperchlorhydria, while in one the gastric secretions were about normal, so that chronic dyspeptic asthma is not constantly associated with any one form of stomach trouble. None of the five patients, however, came complaining of dyspepsia; what they did come for was to obtain relief, if possible, from the distressing shortness of breath from which they suffered. It will also be seen that while an acute attack of dyspeptic asthma, coming on as it does after a meal, is relieved, for the time at least, only by emptying the stomach, the dyspnœa attending the chronic form of the disease, being induced by exertion, however slight, is temporarily relieved only by rest. In one case the sudden attacks coming on at night were always the result of mental worry, and so it is fair to suppose that the attacks of a similar character experienced by two other patients were also due to a disturbed condition of the nervous system. In both the acute and the chronic forms of the disease, permanent relief can come only from restoring the digestive organs to a healthy condition.

A Case of Gangrenous Inflammation of Meckel's Diverticulum Simulating Appendicitis.—By C. R. Darnall. The history of the case is given in full. Death resulted on the third day after operation. On autopsy a Meckel's diverticulum was found springing from the ileum about three feet six inches from the ileo-cæcal valve. It was six inches in length, its distal extremity about one-half the diameter of the other, being firmly attched to the abdominal wall at the umbilicus. It arose from the ileum at a right angle, and at its attachment the diameter was about two-thirds that of the intestine, readily admitting the finger. It gradually diminished in diameter toward its distal extremity. It was patulous throughout its whole extent. There was no torsion or kinking, nor was there any obstruction of the gut demonstrable at the autopsy. At its attachment to the ileum, and for about two inches from that point, the diverticulum appeared to be normal, but at the latter point began a large gangrenous patch which extended along the diverticulum for about one inch and a half, and which at its widest part measured three-quarters of an inch. Near the centre was a perforation about two millimetres in diameter. The diverticulum contained about an ounce of offensive smelling fluid.

Some Remarks on Tuberculosis in Bone.—By Edmund Owen. The article is practically confined to the discussion of tuberculosis of the bones of the hand and foot. In the foot the astragalus is the one most often the seat of primary disease, which generally follows a sprain or twist. At first there are dull pains in the upper tarsal region, and, later, there is some tenderness on making deep pressure, but there is no discoloration of the skin, nor is there heat or œdema. Later the ankle joint is disturbed, effusion occurs, and it becomes stiffened. Under these circumstances Owens finds that the ordinary operation of simply scraping is not radical enough and advises a Syme amputation, which he has often done in hospital practice, though only once in private work, and has not seen any reason to regret it in a single instance. He is not, however, an advocate for radical treatment in all cases of bone tuberculosis, but he believes that amputation with an artificial limb makes life much more endurable in many instances than a resection of a joint with resulting stiffness.

The General Principles of Infant Feeding with Simple Method of Home Modification of Cow's Milk.—By L. E. Holt.

Prevention and Management of Infection of the Breast during Lactation.—By C. S. Bacon.

The Question of Operation in Appendicitis.—By Forbes Hawkes.

Boston Medical and Surgical Journal, Jan. 10, 1901.

The Purulent Rhinitis of Children as a Source of Infection in Cervical Adenitis.—Carolus M. Cobb says that a purulent discharge from the nose may not cause a cervical adenitis for some time, because the retained secretion is very largely contained in bony cavities, but it eventually denudes the mucous membrane over which it flows, and then some condition, as an acute cold, blocks the flow of the purulent discharge and absorption of the retained secretion takes place. If the source of the infection is in the nose, then the importance of treating the nasal disease does not need to be insisted upon. As long as the source of infection remains unhealed, it is hardly reasonable to hope to cure the adenitis. It is true that the infected glands can be removed and the process stopped in them, but this does not prevent others from becoming involved, and one hardly would care to remove the whole lymphatic system of the neck to prevent recurrence.

The Radical Treatment of Lachrymal Diseases.—Walter B. Lancaster says that in many cases in which the usual conservative treatment of epiphora is ineffectual, extirpation of the lacrymal gland and sac, one or both, may be indicated. The surprising thing is that the operation has not become more common. The author has had excellent success with it in five cases. His inclination is toward removing both sac and gland, and not only the large gland but the greater part of the accessory as well. There are some cases in which removal of the gland without the removal of the sac seems to promise relief, and, if so, is to be preferred, namely, cases in which there is no obstruction in the lacrymal passage either to a probe of fair size or to water from a syringe, and yet the epiphora is great. Favorable results in such cases are reported by De Wecker and others.

The Education of the Sense of Touch in Feeble-Minded Children and its Connection with Manual and Industrial Training.—Fletcher Beach states that in order that the sense of touch should be well developed the nervous structures of the skin should be in a normal condition, and common sensation should be fully developed. Sensation, however, in feeble-minded children is much more dull than in ordinary children, and they do not suffer pain to the same extent. Since common sensation is defective, the sense of touch must be cultivated. This may be accomplished by making the child grasp hard and soft, rough and smooth objects, etc. The sensations of heat and cold, too, should be cultivated. After cultivating the sense of touch, the training of the hand should receive careful attention. Co-ordinating power is attained by manual training. The child may pick up and place in their proper holes the marbles on a solitaire board. Later a peg-board may be used. Exercises in threading beads, perforating picture cards, and building bricks into various forms may follow. Size and form boards are useful in cultivating accuracy in grasping objects. The former is a flat piece of wood with variously sized round holes into which are placed the corresponding bits of wood, while the latter consists of a board with variously shaped holes. Thus the child learns to distinguish size and form. There may be used a cushion covered with spots into which the child sticks pins. Easy drawing lessons have their advantage. Dressing lessons —unbuttoning and buttoning clothes, lacing boots, tying bows, etc., are most valuable. Many of the kindergarten occupations are serviceable, such as paper-weaving, sloyd work, clay modelling; carpentering, gardening, cane-making, or brush-making may be taught. Knitting, crocheting, and darning may be added to the list. Girls should be trained in domestic work and in the laundry, and also in sewing. By these methods the sense of touch will be educated and the feeble-minded child will be made a more useful member of society.

Surgical Asepsis of the Urethra and Bladder, with Demonstration of a Device for the Purpose.—Ferd. C. Valentine sums up the salient conclusions on this subject as follows: (1) Perfect asepsis of the urethra cannot be obtained by our present methods. (2) Urinary diluents and antiseptics by the mouth are limited in their action. (3) Washings with piston syringes, however large, must necessarily fall short of their purpose. (4) Asepsis of instruments and hands does not suffice to prevent urethral fever. (5) Urethral fever does not occur when instrumentation is preceded and followed by irrigations. (6) The irrigator devised by the writer seven years ago, and since materially simplified, effectively does the work required in the office. (7) The auto-irrigator, first exhibited before the Genito-Urinary Section of the New York Academy of Medicine at its meeting of March, 1900, enables the surgeon to perform urethral and intravesical irrigations anywhere. (8) The auto-irrigator is a useful adjuvant in the treatment of such gonorrhœics as cannot visit the physician with sufficient frequency. (9) The auto-irrigator offers the simplest method of preventing sepsis in those obliged to catheterize themselves. The essential features of the auto-irrigator are a modified douche-bag, made in one piece, with a tube four feet long, terminating in a shield and nozzle, the special finish of whose tip cannot injure the most exquisitely inflamed meatus. There are detailed directions for the benefit of patients who may use the auto-irrigator in gonorrhœa, as well as cuts illustrating the method of its use. The suitable solutions for this work are also described, and the writer concludes with a few remarks on auto-irrigations in prostatic enlargement.

Euthanasia. A Medico-legal Study.—Louis J. Rosenberg and N. E. Aronstam state that to administer drugs with the knowledge that they will produce euthanasia would not only amount to an indictable crime at law, but it would also be regarded as an incongruity to the ethics of the medical profession and to public morals at large. As a matter of law, it is well settled that euthanasia—in the sense of being a means of producing an easy death—is prohibited. It is an old legal principle that the taking of a life is excused only if it is so done to save a life. Some physicians might, under the pretense of doing a merciful act, really commit a deed of felony. It appears, after considering the matter from all points of view, therefore, that there is ample reason to dread that the practice of euthanasia would, in the long run, cause more harm than good. That is why the law, laboring as it always does for the good of the majority, has logically prohibited it. In no case, therefore, should the physician intentionally or directly cause death. He should at all times do his utmost to alleviate pain, and make the pangs of death as void of agony as possible. By doing so he will have complied with the highest standard of ethics, and will earn the gratitude of humanity.

Fallacies Concerning the Menopause.—George Erety Shoemaker believes that the consideration of fallacies regarding the menopause, prevalent at the present day, must deal not with the terrors of the condition, but with an almost fatalistic neglect of real diseases. The great fatality of cancer is largely due to the fact that hemorrhage and all pelvic symptoms are supposed to be due to the menopause. When a case presents itself to the physician, he should at once proceed to question the patient methodically as to her menstrual history—the normal amount of the flow and the intervals between. The time when the change from normal began to occur should be investigated. If an examination is indicated, it should be undertaken at once and thoroughly. As to fibroid tumors, it is claimed that when they continue to grow, to bleed, and to cause symptoms, waiting for the menopause to cure them is usually a losing game. Operation in these cases is indicated, and should be undertaken before the patient's strength is undermined.

Suggestions on the Treatment of Whooping-Cough.—H. F. Thompson calls particular attention to heroin in the treatment of this disease. This drug allays cough and eases respiration. It reduces the number of respirations, but increases their force and the volume of inspired air. It also exerts a distinct influence in allaying dyspnœa. The explanation of its beneficial action is as follows: The mucus accumulates on the posterior laryngeal wall supplied by the superior laryngeal nerve (the nerve of cough), irritating this nerve and producing most intense cough. If these paroxysms can be aborted by the removal of the mucus from this area, we render the patient less liable to fall a victim to the serious complications of the second stage, and from the antispasmodic and expectorant qualities of heroin we get the desired results.

Wound of the Trachea, with Suture and Union by First Intention.—By E. S. Goodhue.

A Case of Urethrorectal Fistula Cured after a Third Operation.—By Orville Horwitz.

Administrative Control of Tuberculosis.—By Collins H. Johnston.

The Disinfection of Infected Typhoid Urines.—By Norman B. Gwyn.

Leukæmia and Splenic Pseudoleukæmia.—By Everett J. Brown.

Re-Expansion of the Uterus in Labor.—By D. Benjamin.

British Medical Journal, January 5, 1901.

An Address on Acute Dilatation of the Heart in Diphtheria, Influenza, and Rheumatic Fever.—D. B. Lees gives the following clinical indications in cardiac degeneration so often resulting from diphtheria: (1) Feebleness of the pulse wave. (2) Feebleness and diffusion of the cardiac impulse. (3) Extension of the cardiac dulness to the left. (4) Feebleness of the first sound at the apex, with accentuation of the pulmonary second sound. (5) A marked accentuation of the aortic second sound. The heart should be carefully examined, especially by palpation and percussion. Light percussion easily reveals the heart's limits The virulence of diphtheria is more intense in children than in adults. Herein is the marked contrast to the behavior of influenza, which is far more dangerous to adults. In influenza rapid dilatation of the heart frequently occurs, within a day or two after the onset of the disease. In rheumatic fever, even in the most subacute attacks, acute dilatation of the heart seems to be invariably present. It is much less dangerous than that of diphtheria or of influenza, in spite of its greater frequency, this difference depending upon the different effect of the several toxins upon the cardiac muscle. In fatal cases of diphtheria and of rheumatism myocarditis and fatty degeneration, or even destruction of cardiac muscle, are often found; probably similar lesions exist in influenza.

A Case of Renal Colic Attended by the Passage of Casts of the Ureter (Urethritis Membranacea).—J. A. Henton White reports the case of a woman just over sixty, who had suffered from renal colic for twenty years. After a typical attack, the writer examined the urine and discovered albumin, a few blood cells, and a number of semi-transparent mucoid strings about an inch long, and obviously derived from the ureter. Microscopically, they were hollow, elongated, cylindrical bodies of clear mucus held together by a few threads of fibrin, and contained a few small granules and the remains of a few epithelial cells, which occasionally showed a transitional character. The patient was put on an alkaline mixture containing gr. ii. of potassium iodide three times a day and at once began to improve. When this treatment was stopped, the trouble returned, but when the treatment was again resumed the attacks were much alleviated.

The Sex of Patients Suffering from Gastric Ulcer.—R. De S. Stawell quotes statistics which seem to indicate a greater preponderance of males subject to gastric ulcer. The true proportion the writer finds to be five males to six females. The great majority of perforations in females occur between the ages of eighteen and twenty-eight, while in males there is a far more even distribution over the decades of life, making the diagnosis easier in the case of the former. Correct conclusions can be drawn only from a large number of necropsies.

Seborrhœa Treated by Benzene.—Ralph W. Leftwich uses benzene in seborrhœa, applying it with a shaving brush. After this application he uses an inunction: Bay rum and castor oil āā ʒ iss., canth. ʒ ii., aq. Coloniæ ʒ ss., to be used every morning, and the benzene to be repeated about once in five days. The effect upon baldness is very satisfactory. The smell of benzene may be partly concealed by the addition of ol. geranii ♏ x. ad ʒ i. For mild cases of the seborrhœa oleosa type, he combines the benzene with an equal quantity of rectified spirits. No hairs are broken off in the removal of the crust by this method.

Extraordinary Weight of a Fœtus at Term.—W. Egmont Kirby reports the case of a child which directly after birth weighed fourteen pounds fifteen ounces, and was twenty-one inches long. It was very fat. The placenta was large. The mother made a good recovery, but the child died twenty-two hours after delivery.

Clinical and Pathological Notes of a Case of Human Actinomycosis, with Conclusions Drawn from it as to the Nature of the Disease.—By H. E. Littledale.

A Case in which Movable Kidney Produced the Usual Symptoms of Hepatic Colic; Successfully Treated by Nephrorrhaphy.—By Macpherson Lawrie.

Epidemic Arsenical Poisoning amongst Beer Drinkers.—By Nathan Raw, Frank H. Barendt, and W. B. Warrington.

Note on the Dialysis of the Toxins through Collodion Walls.—By M. Armand Ruffer and M. Crendiropoulo.

A Clinical Lecture on Leucocythæmia.—By Robert Saundby.

Ichthyol in Erythema Nodosum.—By Alexander Brownlie.

Urachal Fistula.—By J. M. Renton.

The Lancet, Dec. 29, 1900, and Jan. 5, 1901.

Clinical Varieties of Bright's Disease.—By J. R. Bradford. The author states that we may recognize two forms of acute Bright's disease, one characterized not only by the well-known urinary changes but also by the presence of dropsy, the other in which dropsy is absent and in which the distinction between the acute Bright's disease and mere congestion of the kidney is by no means easy. There are at least two forms of chronic Bright's disease—one in which the patient secretes a scanty, highly albuminous urine and becomes markedly dropsical, the course of the malady being chronic and death occurring usually either from the mere water-logging of the tissues, or from the development of inflammatory complications, or from chronic or subacute uræmia. In the second form of Bright's disease the symptoms often run a latent course for an unknown period and the patient ultimately seeks advice on account of very vague symptoms of ill health, such as wasting, loss of strength, circulatory disturbance, or possibly he does not seek advice until the onset of acute and fatal uræmia. In this form of the disease dropsy is absent, the urine is abundant and pale, and it contains a considerable quantity of albumin. It would seem that not only may chronic Bright's disease be chronic from the outset, but also that the two varieties of chronic Bright's disease are not necessarily different stages in one and the same morbid process, but represent rather the different effects of perhaps the same morbid process.

A Case of Cobra Poisoning Treated with Calmette's Antivenene.—By W. Hanna and G. Lamb. One of the observers was accidentally bitten by the snake in his laboratory. The serum was several years old and possessed only about one-fourth its original strength. The wound was sucked and bled freely. Some half an hour after the bite 18 c.c. were injected half into each flank. Symptoms of poisoning from the snake venom appeared in two hours and a half after the accident and were of the usual variety. While they were still present, some serum, only six months old, was obtained, and half the amount of the first dose injected as before. In the course of two to three hours after the latter injection all symptoms disappeared. There was much local reaction around the bite (tip of the thumb) and also in the entire arm. A slough formed around the site of inoculation in the course of three days and came away in three weeks more. Healing was complete six weeks later. The authors attribute great value to the antivenene, and claim that a fresh supply should be kept in Indian dispensaries.

A Case of Hydatids Primarily Affecting the Lung.—J. Cæsar reports a case occurring in a woman, age not given. The special points in the case were: (1) The very low temperature, which was never above 100° up to within a couple of days before death; (2) the character of the expectoration (very viscid and streaked with blood); (3) the intermittent and severe dyspnœa; (4) the diarrhœa; (5) the fact of the patient having suffered years before from drinking foul water. Tapping of the chest revealed the presence of a pale sherry-colored gelatinous substance in the pleural cavity. Under the microscope broken-down hydatid cysts were found, but without hooklets. Autopsy showed the liver normal in size, the costal and pulmonary pleuræ separated, no discoverable communication between the abdominal and pleural cavities, and the growth springing from or attached to the base of the lung. These latter facts were regarded as proving that the trouble did not originate in the liver.

Membranous Œsophagitis; Expulsion of a Complete Cast of the Œsophagus.—By N. Raw. A man aged forty-six years, who had been a heavy drinker of raw whiskey, was admitted to hospital complaining of a burning sensation in the throat and along the line of the gullet. Swallowing was difficult. Six days later he vomited up, after a violent fit of coughing, a complete cast of the œsophagus eight and a half inches long. It was foul-smelling and of a greenish color. Gastrostomy was done a month later, but he died of asthenia six weeks after operation, not having seemed able to digest his food. The autopsy showed that the membranous process had involved the stomach to some extent, and in the gullet it had involved all the coats down to the muscularis externa.

Filariasis and its Consequences in Fiji.—The most common result is elephantiasis, and the author describes the mode of operation commonly practised. The great size of the masses renders surgical intervention no light task. A full description is given, but cannot be abstracted here. Other results of filariasis are cutaneous and deep lymphatic varix, orchitis, and lymph scrotum. The periodical attacks of lymphangitis from which all the children suffer are called "wagaga," affecting especially the epididymis or cord. It generally terminates in abscess, whereupon the patient returns to ordinary health to await another attack. Each adult has four or five such outbreaks annually. The local scalpel for opening these abscesses is a piece of bamboo sharpened to a point.

Calcium Iodate as an Iodoform Substitute and Gastro-Intestinal Antiseptic.—By W. Mackie. The new compound contains fifty-one per cent. of iodine and in addition sixteen per cent. of available oxygen. From its use in a series of cases the author is inclined to believe that its advantages as compared with iodoform are absence of smell, checking of fetor, prevention of hypergranulation, and the inhibition of undue formation of pus. Further, it can be used where iodoform is inadmissible, as in aqueous solution for such purpose as a gargle or mouth-wash, for washing out the vagina, bladder, uterus, etc. Internally it may be given in solution in doses of two or three grains. It is an excellent preventive of gastric fermentation.

Infective Parotitis after Abdominal Section Affecting Two Other Members of a Family.—By B. Addenbrooke. The patient was a boy aged thirteen years. Abdominal section was done for suppurative peritonitis. Parotitis developed on the third day after operation, but the boy was well on the eighth day so far as the glandular lesion was concerned. Eight days after that he was visited by his aunt, who on the third day after suffered in a similar way, and she in turn infected, three days later, another relative with whom she was living.

A Case of Puerperal Fever Successfully Treated with Antistreptococcus Serum.—By H. E. Waller and F. R. Gibbs. The patient was a primipara of twenty-three. The cervix was slightly torn in two places and the perineum ruptured.

Two stitches were inserted under antiseptic precautions. The patient was in labor thirty-six hours and suffered considerably from shock. Symptoms of sepsis developed on the third day. Serum was used early in connection with other measures. Full clinical notes are given in the original.

A Case of Deformity of the Skull Simulating Leontiasis Ossea Associated with a Condition of Syringomyelia, no Physical Signs of Syringomyelia Present.—By J. S. Collier.

The After-Results in Forty Consecutive Cases of Vaginal Hysterectomy Performed for Cancer of the Uterus.—By A. H. N. Lewers.

A Series of Cases of Actinomycosis.—By R. J. Godlee.

French Journals.

The Rash of Varicella.—E. L. M. believes that the scanty reports of the rash of varicella depend upon its ephemeral duration, and also upon the fact that when it is intense the observer is often inclined to consider the association of scarlatina with varicella. The rash generally precedes the eruption of varicella by about twenty-four hours, though it may appear at the same time, or even follow it. It usually occurs once only, but may recur. Sometimes it is accompanied by no symptoms, but more often fever, an accelerated pulse, and a sudden chill are present. Vomiting has been noted, as well as keen thirst, headache, vertigo, backache, and sore throat. All of these symptoms may be severe. The scarlatiniform rash is the most frequent form in varicella, and it may appear in any region of the body, thus differing from the rash of variola. As a rule, it is scattered in large patches, distributed here and there, and separated by areas of normal skin. Vesicles may develop on the regions invaded by the rash. The rash is not followed by desquamation. It rarely lasts more than twenty-four hours. The diagnosis is generally easy, owing to the rapid appearance of the vesicles of varicella.—*Journal des Praticiens*, December 8, 1900.

Ought Vaccination and Revaccination to be Obligatory?—G. Lemière speaks strongly in the affirmative on the subject. Vaccination is obligatory in France for all children. Revaccination is obligatory for all healthy men, but women and invalids are not bound to this obligation. The writer believes that not only vaccination but revaccination after the end of several years should be obligatory. He quotes Guinon's statement that out of seven hundred and thirty-four nurses employed in the smallpox hospital in London, during a period of ten years, only ten were attacked by the disease. These men had not been revaccinated. All the others who escaped had either suffered from the disease or had been revaccinated. As to the interval between the vaccinations, it is now admitted that revaccination should be practised every five years in children, and perhaps a little less frequently in adults after the age of twenty-five years. Lemière, like Brouardel, thinks that as a matter of national interest in time of peace, and especially in time of war, vaccination and revaccination should be practised throughout the nation.—*Journal des Sciences Médicales de Lille*, December 22, 1900.

Tumors of the Prepuce.—Maurice Péraire states that although many operative procedures for preputial tumors were formerly employed, there are two only which are made use of at the present time: (1) Incision, and (2) extirpation. Although the former may be losing ground, still it ought not to be abandoned. It is to be used in the case of suppurating cysts and in the consecutive fistulæ. It should be complete. The cyst should be entirely removed for fear of recurrence The second method, however, is the method of choice. It should be as complete as possible, and should be followed by careful suturing. An aseptic dressing should be applied. If an extensive ablation of the tumor has been made, it will probably be necessary to skin-graft. The rich supply of lymphatics of the preputial region explains the frequency with which œdema occurs, from the least excoriation, in its loose cellular tissue. It also explains how micro-organisms are transported to inguinal glands causing adenitis, whether venereal ulceration is present or not.—*La Médecine Moderne*, November 21, 1900.

Serum Diagnosis of Tuberculosis.—S. Arloing and Paul Courmont believe that in slightly advanced cases of pulmonary tuberculosis the agglutinating power of serum is almost constant, but in varying degrees. In grave cases with extensive lesions the serum reaction is frequently absent or very feeble. It can also diminish in intensity and disappear in proportion to the gravity of the condition. Results of experiments confirm the clinical findings. The agglutinating power in tuberculous patients is in inverse ratio to the gravity of the infection or to the extent of the lesion. In patients affected by diverse complaints and in whom clinical examination fails to detect certain signs of tuberculosis, serum reaction brings to light many cases suffering from latent tuberculosis. In fact, serum reaction in tuberculosis appears to constitute a rapid proceeding, harmless to the patient, and of great diagnostic value in early tuberculosis, especially in subjects suspected to have beginning pulmonary lesions.—*Gazette des Hôpitaux*, December 1, 1900.

Two Cases of Hereditary Nasal Syphilis.—G. Dupond, after reporting these cases, concludes. Certain atresias which sometimes occur in the nasal fossæ may be the result of hereditary syphilitic infantile coryza. The bad odor is one of the principal symptoms of syphilitic coryza, but it is always easy after direct examination with the speculum and mirror to distinguish specific ozæna from the true ozæna of atrophic rhinitis. In doubtful cases the employment of specific treatment will not only clear up the diagnosis but will also hasten the cure of the patient.—*Journal de Médecine de Bordeaux*, December, 23, 1900.

Münchener medicinische Wochenschrift, Dec. 25, 1900.

Tuberculous Peritonitis.—R. Oehler believes that the good results so often following the operative treatment of this affection are not always to be ascribed to the surgical measure, as he has observed a considerable number of cases in which it seems fair to assume that a cure has been effected spontaneously, and while the diagnosis cannot be absolutely unassailable unless confirmed by actual inspection of the peritoneum and the demonstration of tubercles, the author thinks that emaciation, cachectic facies, slight febrile movement, occasional diarrhœa, and abdominal distention and the presence of ascites or nodular tumors make a sufficiently characteristic picture to render the diagnosis safe. In the demonstration of fluid, in addition to the usual tests, it is often of value to have the patient stand and to percuss the lower abdominal zone first slightly and then with the finger deeply pressed in. If fluid is present, it will gravitate between the abdominal wall and intestine, giving dulness unless displaced by deep pressure, when a tympanitic note may be elicited. Another point of diagnostic importance is the implication of the umbilicus. Like that of carcinoma the infiltration of tuberculous disease is prompt to invade this region, and nodules of varying size are often to be detected about it, the navel itself being everted, reddened, and sensitive to pressure. In brief, the author's conclusions are that tuberculous peritonitis is essentially a disease of childhood; is fatal in about one-half the cases (usually through meningitis or the cachexia), the average duration being from one-half to two years; and, finally, that spontaneous cure is possible, and occurs most often in children.

A Case of Addison's Disease Successfully Treated with Adrenal Tablets.—Paul Edel reports a case which seems to bear positive testimony to the specific action of suprarenal extract in this disease. The patient came under observation after having suffered for six months from a gradually progressive malady which gave the typical symptoms of slowly increasing general weakness, bronzed patches on face, neck, genitals and the mucous membrane of the mouth, and rapid, soft pulse. No remissions had occurred in the course of the disease, which during the first three months progressed steadily, and during the latter three appareutly remained stationary. Fifteen grains of adrenal extract were given twice daily with almost immediate improvement, which was so pronounced that at the end of two weeks the patient resumed his occupation of metal working (contrary to advice, however). At the same time the pigmentation decreased, and at the end of five weeks was scarcely noticeable, but after six weeks of treatment the patient succumbed to an acutely intervening attack of tuberculous meningitis. The value of the adrenin is well shown by the fact that its omission, as soon as the meningeal complication developed, was speedily followed by a return of the pigmentation. The diagnosis was confirmed by autopsy.

Tendovaginitis Capitis Longi Bicipitis.—By S. Goldflam.

Description of an Abortion.—By Althaus.

Post-mortem Appearances.—By Wetzel.

Berliner klinische Wochenschrift, No. 52, Dec. 24, 1900.

Amyloid Degeneration with Special Reference to the Kidneys.—M. Litten has made an elaborate study of this

question, finding that the changes in the kidneys assume several different forms, which are described in full in the original. Concerning the presence of serum-albumin in the urine he finds it most constantly in that form in which the amyloid degeneration affects the large white kidney, the amount being greater than in any other form of kidney disease. Cellular elements are also abundant. Albumin is less frequent in the amyloid contracted kidney. It is more abundant again in the mottled kidney, and is accompanied by more or less blood. In this latter form alone has the author ever seen blood in amyloid kidneys.

A Grave Spinal Symptom Complex Related to an Aneurismal, Serpentine-like Change of a Portion of the Vessels of the Spinal Cord.—By E. Brasch.

Contributions to the Normal and Pathological Histology of the Human Hypophysis Cerebri.—By C. Benda.

Extirpation of the Hypophysis Cerebri.—By F. F. Friedman and O. Mass.

Archives of Pediatrics, January, 1901.

Retropharyngeal Abscess and Adenitis.—Irving M. Snow reports three cases of this rare affection. The symptoms are easily misunderstood and may be erroneously ascribed to a catarrhal laryngitis. The tumor, if large and low down, may press aside the larynx or compress the trachea. All symptoms are much aggravated in the recumbent position. Usually the neck is swollen, the cervical lymph nodes being enlarged, especially at the angle of the jaw, often with fever and constitutional disturbance. The abscess is commonly found at the side of the pharynx behind or below the tonsil, less commonly in the median line. Very often nothing can be seen, then the lower portion of the throat should be explored by the finger. Grave errors in diagnosis will occur if palpation is omitted. No time should be lost in evacuating the abscess.

Clinical Notes on Scurvy in the Island of Cuba.—J. L. Dueñas thinks that the severe forms of infantile scorbutus are relatively rare in Havana. Mild and medium cases are met with oftener. The author is inclined to regard infantile scurvy as a form of progressive pernicious anæmia peculiar to early life, or at all events to accept the existence of a primary alteration of the blood, be that of a chemical or infectious order, to explain the symptoms of scurvy as well as those of progressive pernicious anæmia. The physiological activity predominating in the osseous system during early life could account for the subperiostic localization of the hemorrhages in infancy, as well as the greater frequency of the hemorrhages of the gums when in the course of teething. The extraordinary activity of the process of blood-making at that age should give an explanation of the rapid recovery of patients treated in time.

Malarial Coma in a Boy.—E. P. Stone reports the case of a child of three years and eight months who lived in a locality noted for malarial diseases. He was attacked by fever October 8th. On the 10th he passed into a comatose condition, which lasted about six hours, yielding to a bath at 105° F. continued for ten minutes. Quinine treatment overcame the malaria by October 16th.

Pyelonephritis in Children, with Report of a Case in which Nephrectomy was Successfully Performed.—By Louis Fischer.

Remarks on the Pathogenesis and Prophylaxis of Acute Rheumatic Fever in Children.—By Henry Heiman.

Congenital Stenosis (Spasmodic) of the Pylorus; Recovery.—By Thomas S. Southworth.

L'Union Médicale du Canada, December, 1900.

Treatment of Crushed Extremities by Embalming.—O. F. Mercier has saved a number of extremities by the following process: The patient is placed on the operating-table, wrapped in warm covering, and, if necessary, given injections of artificial serum, caffeine, or ether. The traumatic surface is exposed and irrigated with a 1:2,000 bichloride solution, while foreign bodies, clots, etc., are removed with the fingers, shreds and fragments are cut off, and hemorrhage is stopped. The wound is then stuffed with iodoform gauze impregnated with a mixture of vaseline, boric acid, antipyrin, salol, and a little iodoform, the gauze being pushed into every crevice and opening. A dressing of absorbent cotton and bandages is put on and left in place for several days unless there should be a rise of temperature. It is easy to change the deep dressings, for the gauze does not adhere. When cicatrization is well advanced a dry dressing is often substituted. By this treatment the author claims to have saved wounded members that were doomed to amputation.

Anomalies of the Pinna and Occlusion of the External Auditory Canal.—M. Foucher reports a case of partial deafness in which the external ear appeared normal, except for a cartilaginous excrescence on the tragus. The auditory external meatus, however, was non-existent, being represented merely by a small round opening. Yet the patient could hear a conversation two feet away and the ticking of a watch held to the ear. The patient had six fingers on each hand, the fourth, or ring finger, being double. No treatment of the ear was undertaken, a first attempt to find an auditory meatus having failed.

General Peritonitis due to Intestinal Perforation in a Case of Atypical Typhoid Fever; Surgical Intervention; Death.—By A. Marien and L. J. V. Cleroux.

Ocular Traumatism.—By A. Trousseau.

Norsk Magazin for Lægevidenskaben, October, 1900.

A Slight Epidemic of Cerebro-Spinal Meningitis in Berger.—H. P. Lie and Carl Looft report ten cases which occurred in the first half of the current year, 1900. In four cases spinal puncture was performed intra vitam, bacteriological observations were made, and an examination was made post mortem on one case. The meningococcus was found in all the cases examined, but in two cases it was stained by Gram's method, and in another was stained in this way, after having passed through several generations. The organisms were scanty in number. The spinal fluid was injected into rabbits without causing virulent symptoms.

A Case of "Morbus Cœruleus."—W. Grimsgaard reports the case of a boy aged twelve years, giving in detail the physical signs observed during life, and the clinical symptoms, which were chiefly cyanosis, dyspnœa, and œdema. The autopsy was held under disadvantageous circumstances, the left pulmonary artery having been severed so close to the heart that it was not possible to ascertain whether the foramen of Botallo was open or closed. There were two large openings in the interauricular wall. The pulmonary valves were soldered together in pyramid form, and the posterior aortic valves were also united.

The Hygienic Condition of the Penitentiary of Akershus from July 1, 1894, to December 31, 1899.—By Gottfr. Conradi.

The Hygienic Importance of the Lochia.—By Ingvar.

Some Notes on Sterility.—By O. Christie.

Reviews and Notices.

A Manual of Medicine. Edited by W. H. Allchin, M.D. Vol. I., General Diseases. New York: The Macmillan Company. 1900.

This is a compendium of medicine by numerous contributors. It deals with the diseases excited by atmospheric influences (the infections). It is certainly very instructive, quite complete, and well adapted for teaching purposes. With the exception of a few temperature charts the book contains no illustrations.

The Care of the Child in Health. By Nathan Oppenheim, M.D. New York: The Macmilllan Company. 1900.

This book consists of twelve chapters dealing with the hygiene, feeding, and the educational management of children.

Cancer of the Uterus; its Pathology, Symptomatology, Diagnosis, and Treatment, also the Pathology of Diseases of the Endometrium. By Thomas S. Cullen, M.B. (Toronto), Associate Professor of Gynæcology in Johns Hopkins University. Illustrated. New York: D. Appleton & Co. 1900.

According to the preface of this very large monograph, it is intended to teach the general practitioner how to make an early diagnosis in cases of malignant disease of the uterus. The book is so large, however, that the ordinary observer would hardly consider it a convenient and systematized work of reference, though the specialist will find it to contain an enormous amount of useful clinical and statistical material. There is a voluminous discussion of the pathology and histology of the different types of malignant disease seen in the uterus, and many carefully made illustrations for this part of the subject. We cannot say that any new points of importance in diagnosis have been made, but the old ones have been emphasized and enlarged upon to a very considerable extent. The principle of the treatment of malignant disease of the uterus, as well as of the same kind of disease in other parts of the body, is to operate early and as radically as possible, and as long as surgery is our only hopeful resource this fact cannot be too often emphasized. The descriptions of various operations in this work are clear and satisfactory, and form as good a guide for such work as a written description

can, but there is an unnecessary amount of detail introduced in the description of cases. The tables of cases with the ultimate results as far as could be ascertained are valuable from a statistical point of view, but cover only the cases operated upon in Johns Hopkins Hospital. The book is on the whole a valuable addition to the literature of its subject, but would have been benefited by some condensation.

A Treatise on Nasal Suppuration. By Ludwig Grunwald, of Munich. Translated by William Lamb, M.D., of Birmingham. Eight illustrations, two plates, three hundred and thirty pages. New York: William Wood & Company. 1900.

To advance new ideas or to present old ones in a new light should be the *raison d'être* of book-writing. The volume before us satisfies both these essentials, and the publishers have done well to have this work of Grunwald's translated into English. The first half of the book is devoted to general considerations of the etiology, pathology, symptomatology, and treatment of nasal suppurations; the chapter on symptomatology being especially good. The latter half of the work deals with the special local suppurations. The book has been well translated and excellently presented, and will be of interest to the general practitioner as well as to the specialist.

The Treatment of Fractures. By Charles L. Scudder, M.D. Four hundred and thirty-three pages. Profusely illustrated. Philadelphia: William B. Saunders. 1900.

A book whose chief value lies in its excellent illustrations. The author has added nothing to the knowledge of fractures, and his work is in many respects incomplete.

The Refraction of the Eye, Including a Complete Treatise on Ophthalmometry. A Clinical Text-Book for Students and Practitioners. By A. Edward Davis, A.M., M.D., Adjunct Professor of Diseases of the Eye in the New York Post-Graduate Medical School and Hospital; Assistant Surgeon to the Manhattan Eye and Ear Hospital; Attending Ophthalmic Surgeon to the Babies' Wards of the New York Post-Graduate Hospital; Attending Ophthalmic Surgeon to Bellevue Hospital, Out-door Department; Secretary of the New York Ophthalmological Society; Assistant Secretary of the New York Physicians' Mutual Aid Association; Member of New York State Medical Society, County Medical Society, Academy of Medicine, etc. With 119 engravings, 97 of which are original. New York: The Macmillan Company. 1900.

This work is intended to supply the need of a text-book on ophthalmometry. There are a number of books on ophthalmoscopy and retinoscopy, but none in English on ophthalmometry. The author's management of this subject is quite unique, as a large part of it is taken up by a detailed description of cases practically illustrating the use of the ophthalmometer. There is also an index of these cases which must prove most convenient to the student. The chapters comprise a description of the instrument with rules for its use in cases of simple hypermetropia and hypermetropic astigmatism, compound hypermetropic astigmatism, simple myopia and myopic astigmatism, compound myopic astigmatism and mixed astigmatism.

Bericht ueber die Pestepidemie in Kobe und Osaka, von November, 1899, bis Januar, 1900. Erstattet von Prof. Dr. S. Kitasato, Director des kaiserlichen Instituts für Infektionskrankheiten, Dr. T. Takaki, Dr. K. Shiga, und Dr. G. Moriya. Tokio, 1900.

This report on the plague epidemic in Japan during the latter part of last year is a valuable contribution to the literature of a disease that promises to be of more or less interest to the western world for some years to come. There are chapters on the history of this epidemic, on the agency of rats in the spread of the disease, the symptoms and course of plague as observed at this time, case histories, treatment, and the Japanese laws regarding protection against epidemic diseases, and the quarantine law of the country.

Clinical Examination of the Urine and Urinary Diagnosis. A Clinical Guide for the Use of Practitioners and Students of Medicine and Surgery. By J. Bergen Ogden, M.D., Instructor in Chemistry, Harvard University Medical School; Assistant in Clinical Pathology, Boston City Hospital; Medical Chemist to the Carney Hospital; Visiting Chemist to the Long Island Hospital, Boston. Illustrated. Philadelphia: W. B. Saunders & Co. 1900.

The scope of this work embraces the chemistry of the urine and its relation to physiological processes, with a description of the most modern working methods, both qualitative and quantitative. The subject of urinary diagnosis is handled with the greatest care and detail, including the diagnosis and differential diagnosis of diseases and disturbances of the genito-urinary apparatus, considered locally, generally, medically, and surgically. The most striking clinical symptoms of each disease are also enumerated; and also the characteristics of the urine in certain general diseases. The method of recording urinary examinations together with a list of reagents and apparatus for qualitative and quantitative analysis of urine is briefly considered. This work must prove of great value to the practitioner in general.

A Manual of Syphilis and the Venereal Diseases. By James Nevins Hyde, A.M., M.D., Professor of Skin, Genito-Urinary and Venereal Diseases, Rush Medical College, Chicago, etc., and Frank H. Montgomery, M.D., Associate Professor of Skin, Genito-Urinary and Venereal Diseases, Rush Medical College, etc. Second edition, revised and enlarged, with fifty-eight illustrations and nineteen lithographic plates. Philadelphia: W. B. Saunders & Co. 1900.

The first edition of this work attained a success to which the second has materially added. The authors have revised and rearranged a considerable portion of the volume, but have made no essential change in their expressed views. The colored plates are excellent and add very considerably to the value of the book, which according to the preface is primarily intended for the student and general practitioner. To the latter it must prove a valuable work of reference, well up to date. Stricture of the urethra, though strictly speaking a surgical disease of venereal causation, receives a chapter in this work, as is customary in other books upon this branch of medicine. The book is a worthy addition to American medical literature.

Annales de L'Institut de Pathologie et de Bactériologie de Bucarest. Publiées par Victor Babes en collaboration avec V. Sion. Vol. VI. Fifth year, 1894–95. Bucarest. 1898.

The reviewing of the work of the institute of Bucharest, as represented by the articles that go to make up these annals, makes one wish that there were laboratories similar to the one at Bucharest on this side of the Atlantic. The volume contains thirty papers on scientific subjects prepared by Babes and his pupils; an especially valuable contribution is the opening one by Babes on the duties of the state toward promoting bacteriological research. A critical review of all the articles would be entirely beyond the scope of this notice, but it may be said of them all, that it is by such work as is done in this institute that scientific medical progress in made.

Hernia: Its Etiology, Symptoms, and Treatment. By W. McAdam Eccles, M.S. (Lond.), F.R.C.S. (Eng.), Assistant Surgeon West London Hospital, etc. New York: William Wood & Company. 1900.

The author of this excellent volume has carried out his intention expressed in his preface of offering a "short account of the origin, symptoms, and treatment" of hernia. The subject is so extensive that ordinary sized books will generally be judged by the success with which they systematize information and the clearness with which they present it. This volume offers a comprehensive but condensed account of the different forms of hernia, with the symptoms, treatment, and prognosis. The anatomical characteristics receive attention, and the chapter on the important subject of strangulation contains an excellent discussion of the subject, with some matter arranged in tabular form so as thus to enhance the value of the work as a text-book and increase ease of reference. A good deal of space is devoted to the proper structure and application of trusses, and here as elsewhere in the volume we find many very satisfactory illustrations. The subject of the truss is an important one and does not usually receive quite its full share of attention. The author does not mention any particular operation as preferable when we are attempting radical cure, but apparently prefers to depend upon a careful selection of cases rather than a special method of operating. He gives, however, some useful directions upon the preparation of the patient before operation. The last part of the book is devoted to a discussion of the rarer forms of hernia and a chapter upon the relation of hernia to life insurance and the army and the navy. The volume is a desirable addition to contemporary surgical literature.

A Dictionary of Medical Science. By Robley Dunglison, M.D., LL.D. Twenty-second edition, with appendix, thoroughly revised and greatly enlarged, with the pronunciation and derivation of the terms by Richard J. Dunglison, A.M., M.D. Philadelphia and New York: Lea Brothers & Co. 1900.

An excellent feature of this edition is the marginal thumb letters with which every work of the kind should be sup-

plied as a saver of time and energy. All branches of medical science here find the terms in which they are expressed fully explained, and an insight is given into the relative growth of the various departments. The author's original aim to make each term the caption for an epitome of the existing conditions of medical science has been faithfully carried out by the present editor who, after a long apprenticeship, has not only retained the excellent features of the original scheme, but has added pronunciation by phonetic spelling, and has added derivations, the Greek being given in English letters. The author's portrait graces the first page as a tribute to the twenty-second revision, made over seventy years from the time Robley Dunglison first gave his standard work to the English-speaking medical world. The work stands to-day as a proud monument to his memory and achievements.

Twentieth Century Practice: An International Encyclopedia of Modern Medical Science by Leading Authorities of Europe and America. Edited by Thomas L. Stedman, M.D., New York. In twenty volumes. Vol. XX. New York: William Wood & Company. 1900.

Finis coronat opus. Besides important articles on tuberculosis and yellow fever and a number of miscellaneous shorter essays, this last volume of the set contains the general index to all the twenty volumes. When the three hundred and three pages of the index had been completed and the editor had written his preface, from which an idea of the difficulties of his undertaking may be formed, he must have drawn a long sigh of relief. Several changes in authorship had to be made on account of the illness or death of those who had engaged to write for the work, and the interesting, though sad statement is made that these volumes contain the last literary work done by no fewer than nine authors. The list includes Semmola, Leloir, O'Dwyer, Dujardin-Beaumetz, Oertel, Ernest Hart, Kerr, Grainger Stewart, and Whittaker. This fact must enhance the value of this rather remarkable collection of essays, which will stand, in a manner, as a monument to their labors in and devotion to science. In the present number the bacteriology, pathology, and etiology of tuberculosis are studied by August Jerome Lartigau, of Columbia University. He gives a lengthy bibliography. The symptomatology is treated of by Henry W. Berg, of the Willard Parker and Mt. Sinai hospitals, and the diagnosis, prognosis, prophylaxis, and treatment are set forth in one hundred and seventy-one pages by S. Adolph Knopf, of the New York Throat and Nose Hospital, formerly assistant to Professor Dettweiler, of the Falkenstein Sanatorium in Germany. This article is well illustrated. Tuberculosis of the skin is ably portrayed by John T. Bowen, of the Massachusetts Hospital and Harvard University. The whole gives a most excellent survey of phthisis and other tuberculous affections as they are known at the present day. Wolfred Nelson, of the Quebec College of Physicians and Surgeons, now of New York, writes very entertainingly on yellow fever; Thomas R. Brown, of the Johns Hopkins School, on poisoning by snake venom; Beaumont Small, of St. Luke's Hospital, Ottawa, on mushroom poisoning; James E. Newcomb, of Roosevelt and Demilt Dispensaries and Cornell University, on diseases of the uvula, soft palate, and faucial pillars. Neural and mental defects in childhood are written of by Francis Warner, of the London Hospital and London Medical College. Reviewing the completed library and looking over the long list of distinguished men who have helped make it what it is, congratulations are due them, the publishers, and the editor, who have accomplished an arduous task in a very creditable manner.

Pathology and Morbid Anatomy. By T. Henry Green, M.D., F.R.C.P., Physician and Special Lecturer on Clinical Medicine at Charing Cross Hospital; and Senior Physician to the Hospital for Consumption and Diseases of the Chest, Brompton. Revised and Enlarged by H. Montague Murray, M.D., F.R.C.P., Physician to Out-Patients, and Lecturer on Pathology and Morbid Anatomy at Charing Cross Hospital. Ninth Edition Revised from the Ninth English Edition by Walton Martin, Ph.B., M.D., Assistant Demonstrator of Anatomy, College of Physicians and Surgeons, Columbia University; Attending Surgeon to the Out-Patient Department, Roosevelt Hospital. With four colored plates and three hundred and thirty-nine illustrations. Philadelphia and New York: Lea Brothers & Co. 1900.

Increase in the size of this book was found to be unavoidable on account of the presence of a greater number and larger size of the illustrations and of additional chapters on the pathology of the nervous system, malaria, blood, and the preparation and staining of tissues for microscopical study. There are no less than one hundred and eighty new illustrations. The book is certainly abreast with the times, and is so well known that further criticism seems to be unnecessary.

Medical Diseases of Infancy and Childhood. By Dawson Williams, M.D. Lond., Fellow of the Royal College of Physicians of London, and of University College, London; Physician to the East London Hospital for Children, Shadwell. Second Edition. Revised with additions by Frank Spooner Churchill, M.D., Instructor in Diseases of Children, Rush Medical College, in affiliation with the University of Chicago; Professor of Pediatrics, Chicago Polyclinic. Illustrated with seventy-two engravings and two colored plates. Philadelphia and New York: Lea Brothers & Co. 1900.

The names of the author and reviser of this work are a sufficient guarantee of its excellence. The author states that his object has been to indicate the special incidence of disease in childhood; to elucidate as far as possible the causes of this special incidence; to point out the peculiarities which the circumstances of child-life impress upon familiar diseases; and to detail the treatment rendered appropriate by the nature of the disease itself and by the peculiar susceptibility of the growing organism. In the domain of treatment the author has emphasized the rational basis afforded by pathology, and by clinical observation. The reviser has aimed to adapt the work more closely to the special needs of this country. The prescriptions which are scattered through the text have been conformed to the United States Pharmacopœia. There is an appendix of prescriptions, as in the original edition. Particular attention has been paid to infant feeding. The book as a whole is a most valuable storehouse for practitioners in general but more especially for those particularly interested in the study of disease as it occurs in early life.

Atlas and Epitome of Gynæcology. By Dr. Oskar Schaeffer, Privatdocent of Obstetrics and Gynæcology in the University of Heidelberg. Authorized translation from the Second Revised and enlarged German Edition. Edited by Richard C. Norris, A.M., M.D., Surgeon-in Charge, Preston Retreat, Philadelphia; Gynæcologist to the Methodist Episcopal Hospital and to the Philadelphia Hospital; Consulting Gynæcologist to the Southeastern Dispensary and Hospital for Women and Children; Lecturer on Clinical and Operative Obstetrics, Medical Department, University of Pennsylvania. With two hundred and seven colored illustrations on ninety plates, and sixty-two illustrations in the text. Philadelphia: W. B. Saunders & Co. 1900

As the editor states in his preface, this atlas occupies a position midway between the quiz compends and the more pretentious works on gynæcology. There are many illustrations and colored plates, reproducing the appearance of fresh specimens which will give the student accurate ideas of the condition of diseased pelvic organs. The original text has been carefully followed by the translator, Dr. W. Hersey Thomas. It is concise but comprehensive. The tone of the work is conservative, but this feature will be particularly welcome to the student and general practitioner. The editorial notes make clear the points of resemblance as well as divergence between the author's teaching and that generally accepted in America.

The Retrospect of Medicine: A Half-Yearly Journal Edited by James Braithwaite, M.D. Lond. July, 1900. London: Simpkin, Marshall, Hamilton, Kent & Co. Limited.

This is Vol. 121 of the well-known series, taking in the advances from January to June found in a retrospect of the practical side of medicine and surgery. An alphabetically arranged synopsis in the first one hundred and twenty-eight pages covers a wide range of subjects. The issue is up to the usual average.

A Practical Treatise on Genito-Urinary and Venereal Diseases and Syphilis. By Robert W. Taylor, A.M., M.D., etc. Second Edition, thoroughly revised, with one hundred and thirty-eight illustrations and twenty-seven plates. New York and Philadelphia: Lea Brothers & Co. 1900.

It gives us pleasure to record the appearance of the second edition of this work, which is already a standard for both student and physician. The author's opportunities in his specialty have been very great, and he has made good use of them. His style is clear and concise, and he has chosen his illustrations well. W can find in the first nine chapters on gonorrhœa and its consequences all that is important in the subject epitomized and sifted, so that the author's conclusions follow easily and naturally. Many methods of treatment of both acute and chronic urethritis are given, and what is thought best is recommended. Stricture of the urethra is fully discussed. The various conditions, chiefly surgical, of the genito-urinary system excepting gonorrhœa and syphilis, which are usually included in works upon general surgery, are considered at length from the point of view of the specialist, but the

technique of the more serious surgical procedures does not receive the attention which it deserves, and which is given in works upon general surgery. The best part of the book is upon syphilis, and here we can only say that we believe there is no better work on this subject extant. The author has avoided unnecessary detail and interminable bibliography, and has given us a comprehensive view of the subject in which we can find whatever is of practical use and interest. This second edition will add to the popularity of the book, which, taken as a whole, is one of the best works of reference upon its special subject in any language.

Speech-Hesitation By E. J. Ellery Thorpe. New York: Edgar S. Werner Publishing & Supply Company. 1900. Seventy-five pages.

The author here endeavors to explain the causes and to outline the remedy of this most distressing affection. The remarks are interesting, but the explanations are neither clear nor conclusive.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE COMING CENTURY—VENOUS INJECTIONS FOR PHTHISIS—DISAPPOINTMENTS IN SURGERY—CHRONIC MASTITITIS AND TUMORS—CAUSE OF SEX—HOSPITAL SUNDAY FUND—POISONED BEER—PROFESSORS ROBINSON AND THOMSON—RECENT DEATHS.

London, December 28, 1900.

The close of this century and the opening of the next are subjects constantly turning up in conversation this week of Christmas and holidays. In all departments of knowledge there is a summing up of the progress of the closing century, and medicine follows the fashion. And the remarkable retrospect naturally leads to speculation as to the future. An early fixture is a congress on tuberculosis for next year, and no doubt papers and researches for it are already preparing. But meantime men are not waiting for that. Announcements of their investigations in this scourge of our race are being made. One of these is by Dr. Robert Maguire, whose recent lectures before the Harveian Society have now been published in full or in abstract, and thereby given a wide circulation. The one point which has arrested attention is a somewhat startling suggestion as to treatment by intravenous injections of solution of formic aldehyde. The employment of so potent a substance in this manner certainly required considerable confidence in the opinion of its possible value. But Dr. Maguire had the courage of his convictions and proceeded to experiment on himself. In that way he ascertained the amount that might safely be injected, after which he proceeded to employ the injections in cases of phthisis. In the course of his experiments on himself he underwent a degree of inconvenience, and even pain, which I think few would care to encounter. With too strong solutions he had hæmaturia, with clots in the bladder, dysenteric symptoms, cough, catarrh of most mucous membranes, a thrombus in the injected vein, cramps, faintness—in fact, a series of disagreeable, not to say dangerous, symptoms. Howbeit he ascertained, as I have said, how far he could go without subjecting patients to such dangers, and then used such solutions as he found he could safely do. In most of the cases he was able to say there was some improvement, which is perhaps not very encouraging, considering how often cases of phthisis improve under various plans and subsequently disappoint us.

Dr. Maguire intends to bring the method before one of the societies, so that it may be subjected to full discussion. Perhaps then we shall have not only more details of the results, but the views of other physicians. Until then it may be wise to hold our hands and leave Dr. Maguire to complete the work he has so zealously begun.

Since Dr. Maguire's lectures the Harveian Society has had another meeting (on the 20th), when Mr. D'Arcy Power read a paper on "Some Disppointments in Surgery." He distinguished these from "calamities" which have been so ably treated by Paget, confining himself to minor unsatisfactory results, illustrating them by cases in his own experience. He began with early life and instanced adhesion of the prepuce to the glans after circumcision. Then he adduced the unsightly result after harelip operations if the apposition of the red edges has not been accurate. The recurrence of adenoids, as a fertile source of disappointment to parents, was mentioned and the difficulties that may arise in dealing with imperforate anus. In abdominal operations, those on the kidney often disappoint in some way both surgeon and patient—one cause being the formation of a fistula, a result by no means confined to renal cases. After internal strangulation of the bowel has been relieved by operation, there sometimes occurs the condition described by Paget when the patient "is too exhausted to be conscious of relief and goes on dying, though carefully fed and nourished." Mr. Power has met with the same disappointment after relieving intussusception, and related a case in point. Operations on the appendix are so full of disappointments that it is unwise to promise too much—the most vexatious being the impossibility of finding it, or, when found, of removing it in consequence of masses of adhesions. In one case Mr. Power found the appendix attached to the bladder in such a way that its tip had ulcerated through the walls, thus accounting for pus which had been found in the urine. He divided it, removing the proximal end and leaving the distal attached. The patient made a good recovery and the urine was very soon free from pus. Having touched on the mental disturbances which sometimes follow operations, Mr. Power turned to the bones and joints, in connection with which most surgeons have had their disappointments. So, too, injuries of nerves are most unsatisfactory cases at times, while operations for the relief of neuralgia are always disappointing in some way or in some degree.

The relation of chronic mastitis to tumor formation was the subject before the Pathological Society on the 18th inst. It was brought forward by Mr. F. T Paul, who said he was more and more impressed every year by the tendency of chronic mastitis to end in tumor. Cancerous breasts constantly showed changes indicative of previous chronic inflammation, and breasts removed for mastitis often presented appearances suggestive of commencing cancer. If not the actual cause of cancer, inflammation was, at any rate, Mr. Paul said, a frequent predisposing cause of tumor change in the breast, and made excision advisable in all marked or inveterate cases. He called special attention to the association of chronic mastitis with adenoma in early life, and with the cystic and other varieties of a later period; the marked bilateral mastitis preceding bilateral carcinoma; and the suggestive microscopical appearances of specimens of chronic mastitis

Mr. Raymond Johnson did not think that inflammation passed directly into carcinoma; he thought the histological appearance was different when malignancy arose; probably a second, unknown factor was concerned The inflammatory process would not account for all cases of adeno-fibromata. This view was indorsed by other speakers.

Mr. Shattock referred to the possibility of a parasitic origin of cancer, and thought that whatever the nature of the so-called cancer bodies, their presence in a border or doubtful case of carcinoma might be diagnosed.

The causation of sex is a problem still unsolved, though in all ages it seems to have excited curiosity. The Obstetrical Society discussed it on December 2d, apropos of a paper by Mr. Rumley Dawson, who professed to offer "a new theory," and seriously propounded as such a notion as old as literature and probably the very oldest speculation of mankind on the subject The sex of a child, he says, depends on which ovary has been fertilized—if the right the result is a male, if the left a female. Quite ancient writers have not only said this, but have declared that the sex may be determined by the mother lying on one side as soon as copulation has taken place. Mr. Dawson's theory had been proposed centuries ago, and has often been shown to be incompatible with facts. Mr. Doran asked if Mr. Dawson believed that the removal of a queen's left ovary would prevent disappointment of a nation's hopes? Other speakers pointed out that birds have only one ovary, the left, and asked whence the cocks; why cases of one-sided ovariotomy were followed by children of the other sex—if the theory were true—and one case followed by twins, one child male, the other female. Mr. Dawson tried to explain these, and heaped up many facts not inconsistent with his opinion, but there are too many which cannot be explained in this way.

The Hospital Sunday Fund has suffered from the demands caused by the war, and there is a decrease of more than £2,300 in the congregational collections. At the annual meeting on the 20th inst. the report was adopted and June 16th fixed for the collections in 1901. The total amount raised was £51,993 14s. 6d.

Beer poisoning still occupies attention. There have been three more deaths, and the inquests have been adjourned to the same date as those previously reported, when the facts will, it is said, be duly set forth. Cases are reported and various observations made in our journals, but it is too soon to sum up the general conclusions to be drawn.

Dr. Arthur Robinson succeeds the late Professor Hughes in the chair of anatomy at King's College.

The chair of anatomy at the Royal Academy has been given to Dr. A. Thomson, professor of the subject in Ox-

ford University and author of a handbook of anatomy for art students.

Another civil surgeon at the front has fallen—Dr. F. G. Engelbach. He was killed in the fight at Nooitgedach while attending the wounded under a hot fire. Among other deaths I may mention: Dr. Kay-Shuttleworth, our vice-consul at San Remo, where he had practised since 1882; Thomas Taylor, an octogenarian, who died on the 23d at Bocking, in Essex, where he spent all his professional life.

THE HEART REFLEX AND THE NAUHEIM BATH.

To the Editor of the Medical Record.

Sir: The last issue of the Record contains a brief but exceedingly valuable article on the heart reflex, evoked by rubbing or tapping the chest, and its significance in producing recession of the cardiac area after the Nauheim bath. These observations are the more valuable because they are demonstrated by an exact apparatus, which renders them independent of the preconceived notions or impressions of the observer. My interest in this subject was awakened several years ago by the excellent monograph of M. Heitler ("Ueber die Wirkung thermischer und mechanischer Einfluesse auf den Tonus des Herzmuskels," Wien, 1894). In the article on Hydrotherapy and Mineral Springs, which opens the fourth volume of Hare's "System of Practical Therapeutics," I ventured (p. 35), in discussing the diminution of the area of cardiac dulness after the Nauheim bath, to say, "How much of this diminution of area of cardiac dulness may be due to the actual effect of the baths and exercises, and how much to the percussion over the area, which is resorted to for the purpose of outlining it, remains in doubt, when we consider that M. Heitler has shown by actual experiment that an enlarged area of cardiac dulness was invariably diminished by tapping over it." The exact observations of Dr. Abrams have removed this doubt, and the fact may be regarded as established that the cardiac recession is due partly, if not altogether, to the evoking of Abrams' heart reflex. All doubts may be removed by obtaining a fluoroscopic picture of an uncompensated heart, before and after the Nauheim bath, without first subjecting the cardiac area to percussion or friction. There is nothing so much needed in medicine as precision in the statement of observation and exactness in making the latter. Surgery has emancipated itself from the mysticism of the past and is now reaping benefit from the discovery of the positive fact that upon absolute cleanliness depends success of surgical measures. Our therapeutic ideas are still too much under the dominion of the empiricism of the past. Every ray of light which removes doubt and substitutes exactness should be gratefully received.

The Nauheim bath emphasized this view. Its great value in certain serious cardiac conditions has been firmly established by the clinical observations of many physicians who cannot be charged with bias or interest in the springs. It is a singular illustration of the above statement that the fanciful *rationale* of the action of these baths, announced by T. Schott, has been accepted by observers of more scientific attainments, who seem to have been hypnotized by the truly marvellous results of these baths. I ventured to write (*ibid.*, p. 34): "The *rationale* of the system of mineral baths and resisting movements is explained by Schott, by assuming a reflex stimulating influence upon the cardiac inhibitory centre, by reason of which the pulse is slowed, its tone increased, and the blood pressure heightened. It would seem that a far more simple explanation may be found in the well-known stimulating or tonic effects upon the circulation (reflex and hydrostatic) always produced by brief applications of water at temperatures below the normal, which stimulation is enhanced by the mineral constituents and the CO_2 gas bubbles, which exert an irritant mechanical effect upon the large cutaneous area. Under this stimulus the cutaneous vessels are dilated—as indicated by redness of the skin when the patient emerges from the bath and is rubbed with a warm cloth. The physiological result of this stimulus to the cutaneous vessels (vasomotor gymnastics of Kellogg) is an increase of blood pressure, a more vigorous systole, and a more complete emptying of the vessels. The dilatation of the cutaneous vessels under reaction after a bath ten to fifteen degrees below the temperature of the body, aided by the stimulating effect of the CO_2 globules and salines, is not the result of relaxation, as it would be after a bath of a few degrees above the normal temperature, but of stimulation to the vasodilators on the skin, endowing its vessels with increased elastic propulsive power. The blood is more vigorously propelled through the enormous area of peripheral vessels, and sufficient normal resistance is created in the latter to increase the blood pressure. There is no need of resorting to Schott's undemonstrable theory, if we can explain the effect of the baths upon this simple *rationale* based upon well-ascertained physiological laws. The great value of the salines and CO_2 contents in the Nauheim water resides in their warming the skin and thus enhancing reaction, which would be imperfect in patients of normal temperature and usually feeble reactive power, without using friction. In other words the mineral ingredients of the Nauheim water take the place of friction, which every judicious hydrotherapist uses when administering baths below the body temperature, in order to prevent chilling, which he abhors. This explanation of the *rationale* of the action of the Nauheim bath disposes of the contradiction involved in the *rationales* offered by Schott, Bezley-Thorne, Saundby, Broadbent, and others. While according, therefore, to the Nauheim baths all that is claimed for them, especially when taken in the lovely village, endowed by nature with valuable springs and beautiful groves, which lure the patient to calmness, the theory of their effect must be reconstructed and simplified." I cannot quite agree with Dr. Abrams' "theory that the real factor involved in balneo- and mechanico-therapeutics (Schott) is dependent not on the baths and exercises as such, but owing to the cutaneous irritation provoked by these manœuvres." The great recessions of cardiac dulness reported by many are doubtless chiefly due to the percussion instituted for ascertaining it; but the enduring improvement of the systole and the consequent better filling of the arteries and increase of urine, the enhancement of the general health and restitution of lost compensation, can be explained only by the oft-repeated reaction from the cool bath in water containing stimulating saline and CO_2 ingredients, and their effect upon the cutaneous circulation. The latter, being an essential part of the vasomotor system, is thus restored or enhanced, and restores or enhances the entire circulatory apparatus. This *rationale* applies to every cold hydrotherapeutic procedure administered in chronic diseases, and partly explains also the effect of the valuable Brand bath in typhoid fever. In the latter I have often utilized the Nauheim salts for the purpose of overcoming feeble reactive capacity in patients, who otherwise could not accept any cool bath without chilling and depression.

Simon Baruch, M.D.

51 West Seventieth Street, New York.

REST IN BED IN THE TREATMENT OF ACUTE MENTAL DISEASE.

To the Editor of the Medical Record.

Sir: In the number of your journal for December 22, 1900, on page 976, you quote from the *Archives de Neurologie*, October, 1900, the description of a method of treatment of the acute forms of mental disease by rest in bed, and the quotation also refers to the advantage of carrying out this method in a large open ward. It may interest you to know that this plan of treatment has been in use in this hospital for the past seven years, successfully, with all of the advantages referred to in your quotation manifest. However, we go still further and put every patient received in bed; keeping him there until by careful clinical investigation, with the aid of the laboratory, we know to what extent he may be suffering from organic disease or functional disturbance in the vegetative organs. To quote from a recent paper by the writer: "If the patient is ushered into a cheerful ward and received by properly gowned nurses, who give him a bath and put him in bed, he realizes that he is being cared for, even if he does not think such care necessary. After a careful examination by the physician in charge his confidence is more fully gained and he submits to whatever treatment is necessary without resentment. The occasional patient, who is maniacal or delirious, does not interfere with the general plan; and his management need not differ from that of similar cases in a general hospital, having delirium as a complication."

I was surprised at the reference in your quotation to "solitary confinement in cells." I did not suppose that the insane were now treated as dangerous criminals or wild animals in any country. The good effect of treating the insane as you would other sick people cannot but be apparent to any one who has tried the method, as well as the great advantage of caring for recent cases in a large open ward, where the presence of others serves to attract the attention of the patient away from himself. But in order to appreciate the significance of such methods, one must rid himself of the metaphysical conception of what is constituted in insanity and of all mediæval ideas as to its treatment. The "mind" is not an entity, but the functioning which it represents is purely physical, and it is the expression of the sum of all activities comprehended in life.

H. A. Tomlinson, M.D.

St. Peter State Hospital, St. Peter, Minn.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Annual Meeting, January 3, 1901.

ROBERT F. WEIR, M.D., PRESIDENT.

Address of the Retiring President.—DR. WILLIAM H. THOMSON, on retiring from the presidency of the academy, delivered a short address, which was largely reminiscent, and which pointed out the many advances made in medicine and the great responsibility of the physician. A very recent illustration was cited to show the important rôle now played by blood examinations. A woman had come to him with an obscure mass in the abdomen, near the liver. She had been supposed to be suffering from malaria, but this had at once been excluded by a microscopical examination of the blood. This examination had shown, however, such a marked hyperleucocytosis that an exploratory operation had been advised, and done. The operation revealed extensive adhesions about the liver, and a gall bladder containing seventy-six stones and a quantity of pus.

Inaugural Address of the President.—DR. ROBERT F. WEIR delivered this address. He said that his admission to the Academy of Medicine in 1881 had occurred at an important epoch, *i.e.*, when the prosperous New York Journal Association was merged into the academy. This had led at the time to his being vice-president of the academy. The academy had been carried through troublous times with great tact and ability by the late Dr. Fordyce Barker while occupying the presidential chair from 1879 to 1885. To Dr. A. Jacobi was due great credit for having divided up the work of the academy into sections. The section meetings he considered exceedingly important, though he was well aware that some looked with dismay upon the very prominent part they had taken in the work of the academy. A question of no little importance was, Why did the membership of the academy grow so slowly? The answer was perhaps to be found in the amount charged for dues, and this suggested that it would possibly be found advisable to modify the rules in regard to them. The lack of interest in the general meetings as compared with the section meetings was probably because of the system by which the work of the sections was carried on almost independently of the academy.

Presentation of a Portrait.—A portrait of the late Dr. John Hoskins Griscom was presented to the academy by his daughter, Frances Griscom Parsons. Dr. Griscom was an original fellow of the academy, and its vice-president in 1854. He died in 1874.

Memorial Address on the Life of Dr. Lewis Albert Sayre.—DR. LEROY M. YALE read this address. He said that Dr. Sayre's connection with hospitals dated back to 1853, and that he had been actively connected with Bellevue Hospital for thirty-one years. Throughout his early life he had taken an active interest in medical societies, and as but few were in existence at that time, he had come to be one of the founders of many of them, notably of the New York Pathological Society and of the American Medical Association. His first hip-joint exsection had been done in 1851, and was the first operation of the kind in this country. To understand fully the position of Dr. Sayre in 1866 it should be recalled that at that time there was almost no teaching of orthopædic surgery, and that joint diseases were treated either by a clumsy workman under the rather vague directions of the surgeons, or by a more skilled workman who essayed to treat joint diseases mechanically, though having little or no knowledge of the nature of such diseases. While it was too soon to express a positive opinion regarding the influence of Dr. Sayre on the medicine and surgery of his time, it was safe to claim that in the future whoever would go over the history of American surgery would find that Dr. Sayre had taken an active part at every stage in its progress.

SECTION ON OBSTETRICS AND GYNÆCOLOGY.

Stated Meeting, December 27, 1900.

J. RIDDLE GOFFE, M.D., CHAIRMAN.

Spina Bifida; Treatment by Injections of Iodine.—DR. E. A. AYERS presented a child six weeks old, with a spina bifida. It had been born by the breech. He had operated on December 12th. The tumor was about the size of a mandarin orange. The vertebral arches were wanting over two of the vertebræ. The sac was transparent, and the cauda equina could be seen floating in the fluid beneath the skin. He had operated by injecting ℥ xxv. of pure tincture of iodine. The injection had been made in the thicker portion of the skin at the side in order to prevent leakage. The site of the puncture and the entire sac had been painted with collodion daily for several days. For two days after the operation the child had had opisthotonos. The tumor had been very greatly reduced in size. According to the statistics of this operation there were about forty per cent. of recoveries. He had operated about three times by opening the tumor, and all the cases had terminated fatally. On account of the constitutional condition of the child—the tendency to marasmus—and the fact that the mother would not leave the child in the hospital where it could be properly cared for, he did not think the outlook was very good.

Congenital Hypertrophy of the Cervix and Bilateral Salpinx in a Girl of Seventeen Years.—DR. A. BROTHERS said that at the age of fourteen the womb had been noticed to be projecting from the vulva. A diagnosis of prolapse of the uterus had been made, and Alexander's operation had been done by an eminent gynæcologist in one of our hospitals. This had given the girl no relief. She had finally come under his observation on November 3, 1900. The cervix was found projecting one inch from the vulva, and the anterior and posterior vaginal walls were also prolapsed. The uterus was decidedly enlarged, and palpation revealed bilateral pyosalpinx. On November 10th the uterus and ovaries had been removed by him; the patient had left the hospital on the sixteenth day, and was now perfectly well. More than one-third of the uterus was found to consist of cervix. This hypertrophied cervix had evidently been overlooked two years ago when the Alexander operation had been done. The bilateral salpinx had almost surely resulted from infection by the indiscriminate use of the uterine sound by medical practitioners who had examined her.

Early Ruptured Ectopic Gestation.—Dr. Brothers also presented specimens from three cases of intraperitoneal hemorrhage, presumably from extra-uterine pregnancy.

DR. A. PALMER DUDLEY strongly condemned the resort to vaginal hysterectomy in the case of the young girl with congenital hypertrophy of the cervix. Two healthy ovaries, he said, had been removed, yet it was quite possible in a case of non-specific pyosalpinx to wash out the tube and thus do conservative surgery. The tubes in this case should have been resected and washed out, or a portion left; then a portion of the cervix should have been amputated, and, if necessary, a hysterorrhaphy done to anchor the uterus in a proper

position. At the present day, a vaginal hysterectomy upon a girl of seventeen, in a case presenting no history of specific infection, was certainly a most questionable procedure. He made this statement, not as a personal criticism, but from a purely scientific standpoint.

Dr. Louis J. Ladinski asked for proof of the statement that this was a case of congenital hypertrophy of the cervix. He had under his care a girl of fifteen years who, when eleven years of age, had been presented to that section. Both body and cervix were greatly enlarged, and during all these years the girl had been suffering from menorrhagia and metrorrhagia. She had been curetted many times, and the scrapings repeatedly examined, but always with negative result. When this girl was not quite eleven years old the uterus had been as large as that of a woman of thirty-five, and he had come to the conclusion that the case was one of precocious maturity. The case just presented seemed to him probably a similar one of unusual development of the uterus.

Dr. Goffe also criticised the very radical method of treatment employed in this case. He would have preferred to attack the case by the vaginal route, doing conservative work on the ovaries and tubes.

Dr. Brothers said that the girl had not come to him with a diagnosis of congenital hypertrophy of the uterus, but with a protruding and eroded cervix, a purulent discharge, a temperature of 101° F., and a general septic condition. He had tried ventral fixation in other cases and had failed in properly fixing the uterus, and owing to the very bad condition of this girl it had seemed to him perfectly justifiable to do hysterectomy. In doing this for complete prolapsus he had followed in the footsteps of many authorities, chiefly foreign, and if he had erred, then it was because these teachers had erred.

Ruptured Interstitial Pregnancy.—Dr. L. J. Ladinski presented this specimen. For about three months previous to coming under observation there had been amenorrhœa and irregular hemorrhages and abdominal cramps. He had first seen the patient on October 4th at the Beth Israel Hospital. Her temperature at that time had been 101.5° and the pulse 108 and very feeble. The abdomen was greatly distended and tender, and apparently there was fluid in the lower part of the abdomen. There was in the right cul-de-sac a fluctuating mass which was intimately adherent to the uterus. There was a bloody discharge from the uterine cavity. The operation had been done under ether narcosis. When the abdominal cavity had been opened a quantity of dark blood and clots had escaped. The right Fallopian tube was ruptured and there was hemorrhage from the rent. Examination showed plainly that the case was one of interstitial pregnancy. The patient had made an uneventful recovery. In tubal pregnancy rupture usually took place before the second or third month, whereas in interstitial pregnancy the rupture usually occurred much later. By interstitial pregnancy was meant a pregnancy in the portion of the tube within the uterus; it was often confounded with cornual pregnancy. The differential diagnosis was not easy, but in interstitial pregnancy the round ligament would be found to the inner side of the sac, whereas in cornual pregnancy it was on the outer side.

Dr. Ladinski also presented for diagnosis a specimen removed from a woman forty-one years of age. She had given a history of uterine hemorrhage, nausea, and abdominal pain. A cystic mass could be distinctly felt through the left vaginal fornix. On October 20th she had been operated upon. The left ovary had been found cystic and the fimbriated extremity of the tube distended. A similar condition had been found on the right side, and both tubes were removed. The mass in the pelvis proved to be an encapsulated blood-clot. He had considered the case a tubal abortion, but it had been repeatedly examined and no chorionic villi found.

Multiple Myomectomy for Fibroids.—Dr. George Gray Ward presented seven fibroids removed from a widow forty-seven years of age. She had sought relief chiefly because of a marked irritability of the bladder. On abdominal section he had found that the irritability of the bladder was due to fibroids pressing deeply upon the bladder and preventing the proper distention of this viscus. As there was not a general fibroid condition of the uterus, myomectomy had been done. The interesting points of the case were the remarkably smooth convalescence and the complete relief of the bladder symptoms.

Vaginal Hysterectomy for Complete Prolapsus Uteri.—Dr. Ward exhibited this specimen, which had been removed by operation from a woman sixty years of age, who had been incapacitated from work and had been in wretched health because of the condition of the pelvic organs. She recovered from the first operation nicely, and three weeks later he had done an anterior and posterior colporrhaphy and a perineorrhaphy. When seen three months afterward there was no stretching of the scar in the anterior wall. This was probably largely owing to the fact that the patient would not keep quiet for a sufficient length of time.

The Glass-Ball Pessary.—For relief of the cystocele he had followed the advise of his old preceptor, the late Dr. Skene, and had inserted a glass-ball pessary. These pessaries could be worn with safety and comfort for an indefinite time by women who had passed the menopause, and in whom there were no longer menstrual or other irritating discharges.

Dr. H. J. Boldt said that he had been very unfortunate with this class of cases, except in the use of hysterorrhaphy, but in such a stout patient as Dr. Ward's he would also prefer the method adopted. According to his own experience, hysterectomy was not a good procedure, and the only satisfactory one was ventral fixation. The latter operation should be done in such a way as to give a broad and firm adhesion between the abdominal parietes and the uterus. As a rule, plastic operations would not be required after the ventral fixation. He had known one woman to improvise for herself a ball pessary out of beeswax. This she had worn for two or three years.

Dr. Goffe described a method of operating by making V-shaped incisions on either side and tucking the broad ligaments into these. In every case in which he had used this method a permanent cure had been effected.

Spontaneous Delivery of a Uterine Polypus.—Dr. Kinch, of Westfield, N. J., presented a specimen removed from a German woman twenty-nine years of age. She had menstruated regularly on July 1st, and on the 16th had again had a flow associated with abdominal pain. Two days later examination had shown the os dilated and a mass protruding. This mass proved to be a fibroma weighing eighteen ounces. It was detached and delivered with the aid of forceps. The patient rapidly recovered, and had since menstruated regularly and without discomfort.

Ectopic Gestation; Stump Infection; Perforating Gastric Ulcer.—Dr. Philander A. Harris, of Paterson, N. J., presented several specimens. The first was one of ruptured tubal abortion with death in twenty-seven hours. The rupture occurred about five weeks after the last menstruation. The second case was similar to the first, except that the patient had recovered. The third specimen was one of tubal rupture in the broad ligament, occurring in the sixth week after the last menstruation. The patient was operated

upon and recovered. The fourth specimen was one of rupture at the eighth week, and the fifth a pus tube and ovary removed from the other side of the same patient. The next specimen was a tube and cystic ovary. At the operation blood had been found pouring from the tube. He took the case to be one of ectopic gestation. The next specimen was the body of the uterus removed from a lady who had had the tubes and ovaries extirpated by the late Dr. Lusk some years before. The specimen was a good example of stump infection. The last specimen was one of perforating ulcer of the stomach. The woman had been admitted to the hospital with symptoms pointing to the possibility of an ectopic gestation, but while she was given ether preparatory to an exploratory laparotomy she had suddenly died. The autopsy had revealed the presence of a gastric ulcer and of four or five pints of pus in the peritoneal cavity. The examination of the pelvic organs was negative.

The Use of the Paquelin Cautery in the Uterine Cavity.—Dr. J. A. Schmitt read this paper. He said that of all the forms of intra-uterine therapeutics curettage took the first rank, but in the hands of the average practitioner it was an operation of questionable value. He maintained that the curette was a most dangerous instrument, and should be banished from the puerperium. In using the Paquelin cautery within the uterus he placed the patient in the side position and under narcosis. Short cylindrical vaginal specula of hard-rubber or glass were employed. Having determined the length and direction of the uterine canal by the use of the uterine sound, the canal should be dilated and irrigated, first with bichloride, and then with Thiersch solution. The red-hot cautery was then introduced and drawn successively over the different portions of the cavity, first over the anterior, then over the posterior surface, next over the sides, and lastly over the fundus. Bichloride irrigation and the tamponade completed the operation. This heroic treatment he thought should be restricted to those cases of puerperal sepsis in which, after careful examination, the conclusion had been reached that the site of the infection was within the uterus, and the more usual methods had failed to check the proc ess. A number of cases were reported in illustration of the method and its results.

Dr. H. J. Boldt said that he understood that the reader of the paper made use of the cautery with great freedom, claiming that by experiments on pieces of meat he had demonstrated to his own satisfaction that it was difficult to perforate the uterus. To this comparison between the uterus and pieces of meat he would take exception, and would state very candidly that there seemed to be no great difference, as regards the liability to perforation, between the curette and the cautery, and every one knew how easy it was, even in the most careful hands, to perforate the uterus. This was especially true of the uterus in the class of cases in which the author employed the method chiefly, *i.e.*, in cases of septic endometritis. Again, he would like to know what was the condition of the uterus in such cases some months after having been subjected to the cautery. It was well known that when steam had been used in the uterine cavity it had, in some instances, completely destroyed the utricular glands.

Dr. A. Palmer Dudley said that if he remembered correctly this was not a new practice, the hot iron having been tried years ago by Sims, and found wanting. He raised the question whether the use of the hot iron within the uterus would relieve a salpingitis, or a cellulitis, or a lymphangitis in the pelvis in cases of sepsis. Supposing the hot iron did prevent the action of the gonococcus within the uterus, would it, he asked, prevent the multiplication of this organism in the tubes? He was also desirous of knowing what would be the functional condition of the uterus after such treatment. Of the two instruments, the curette and the cautery, he greatly preferred the curette.

Dr. Philander A. Harris said he would place this procedure on a par with the use of chloride of zinc and similar agents. He was of the opinion that even if the uterus were in the operator's hand and were split open, it would take some time to apply the Paquelin cautery thoroughly to every part of the interior of the uterus. After the septic process had spread beyond the uterus he believed the latter was no longer a fertile source of sepsis—indeed, the uterus appeared to sterilize itself in a few days.

Dr. E. A. Ayers said the author had not in the paper presented any evidence of the final results of the treatment. The latter was largely carried out by the sense of touch, for little could be seen when the cautery was introduced through the speculum, and it seemed to him really an experiment in vivisection, and one which should be condemned until strong evidence in its favor could be adduced.

Dr. Goffe said that the amount of destruction produced by the actual cautery seemed to be an unknown quantity, and if it did act efficiently it probably also destroyed useful portions which would not be replaced. The unfortunate consequences of eschars in the uterine cavity were well known and should lead one to be cautious about adopting such a method of treatment.

Dr. Schmitt closed the discussion. He said that he was not in a position to state the extent of destruction produced by the cautery; he could only say that the results of this kind which he had at first feared had not been met with in practice. He inclined to the belief that the endometrium was partly or wholly covered again with epithelium. Some remnants of the uterine glands were always left, and from these new epithelia and muscle probably developed. When the septic process had extended beyond the uterus he did not employ the method.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 14, 1900.

Eugene Hodenpyl, M.D., President.

A Case of Congenital Deformity of the Heart.—Dr. N. B. Potter reported this case, which occurred in a child supposed to have been perfectly well up to the age of two years. At this time there had been an attack of cholera infantum, and the attending physician announced that heart disease was also present. The speaker said that he had seen the child in a hospital last December, and at that time there had been marked clubbing of the fingers, associated with marked cyanosis and dyspnœa. There was also an otitis media on the left side. The child had, however, recovered, and had remained perfectly well up to October 1st. Symptoms of meningitis had then made their appearance, and death had occurred ten days later. The autopsy revealed an abscess, the size of a large lemon, in the right frontal and parietal regions. There was a basilar meningitis. The cultures from the abscess and from the meninges were sterile. It was remarkable that such a large abscess could exist for so long a time without giving rise to symptoms. Examination of the heart showed the right ventricle to be nearly absent. The blood came from the vena cava through the foramen ovale into the left auricle, and from there passed to the left ventricle and thence to the aorta. The blood supply to the lungs came from a branch of the aorta. A loud systolic murmur had been audible during life all over the precordium without any particular spot of maximum intensity.

A Case of Rupture of the Spleen; Malaria.—Dr. Potter also reported the following case: A sailor had been admitted to hospital with a chill, and had died shortly afterward in spite of large doses of quinine. The organism of æstivo-autumnal fever had been found in his blood before death. At autopsy, a rupture of the spleen in the posterior and superior portions had been found. It was the kind of rupture seen as a result of violence, though there was no history of such traumatism. He did not think the rupture of the spleen had been the cause of death. Less than one pint of blood had been found in the abdominal cavity. The spleen weighed one pound six and a half ounces.

Dr. David Bovaird said that this congenital anomaly of the heart was interesting, because of its peculiar association with abscess of the brain. This association had been noticed repeatedly, but so far no adequate explanation had been offered. This was the third case of the kind that he had seen.

Dr. O. H. Schultze reported several cases. The first was a case of apparent spontaneous rupture of the spleen occurring in a male adult suffering from malaria, reported by kind permission of Dr. E. J. Donlin. The deceased had been found dead in his room by the coroner's physician. From the fact that there had been well-marked post-mortem hypostasis in the frontal region, and in addition secondary hypostasis on the posterior aspect of the body, he had been led to believe that an interval of eight or ten hours had elapsed from the time of the man's death, until he had been turned into the second position. About two quarts of fluid but also clotted blood had been found in the peritoneal cavity. The source of this hemorrhage was a laceration of the spleen. This organ looked like a mass of thick chocolate, and no portion could be absolutely identified as the spleen except a small shred of capsule. Some of this softened tissue had been examined microscopically, and identified as that of the spleen. It contained a considerable quantity of dark pigment. A smear from the bone marrow had been made, and was exhibited to the society under the microscope. It showed quite a number of spheroidal bodies and pigment resembling melanin in the red-blood cells. This person was a steward, forty-five years of age, who was said to have suffered from malaria for about three weeks. There were absolutely no external marks of traumatism. This, in itself, did not warrant a diagnosis of spontaneous rupture of the spleen, but from the appearance of the softened tissue and the blood in the region of the spleen, he felt warranted in looking upon this as a case of malaria with spontaneous rupture of the spleen.

Dr. Schultze also reported the following case: A man thirty years of age had been admitted to Bellevue Hospital on August 22d. He had complained of severe pain in the epigastrium, and of having vomited on the preceding day. The bowels had not moved for four or five days, and the diagnosis of his physician had been intestinal obstruction. On the following night the operation of colostomy had been done, and no peritonitis had been noted at that time. The man had died very suddenly and unexpectedly about twelve hours afterward. At the autopsy there had been found a considerable degree of hemorrhagic pancreatitis with fat necrosis. The surface of the peritoneal fat showed throughout minute areas of fat necrosis. In some places this fat necrosis extended some distance below the surface of the tissue. The mistake in diagnosis was very pardonable, as the condition had often been confounded with intestinal obstruction.

Dr. Schultze presented a third case. The subject was a man about forty-five years of age, who had been brought to Bellevue Hospital by the Hudson Street Hospital ambulance suffering from epigastric pain and vomiting. He stated that he had been pushed against a wagon and run over, but the autopsy had shown no evidence indicative of injury. He stated that at the Hudson Street Hospital he had been catheterized because of retention of urine, and that he had been bleeding since that time. There was some bleeding from the meatus, and on several occasions while in Bellevue Hospital it had been necessary to catheterize him. In the intervals of catheterization a small quantity of blood had been passed. It was said that the passage of the catheter had been very difficult, but there had been no infiltration of urine or any hemorrhage into the perineum. On the third day external urethrotomy had been performed, and the bladder had been explored digitally with such vigor as to cause laceration of the prostatic urethra. At autopsy the bladder contained blood clot about two ounces in amount, but no blood had escaped through the wall. A large amount of fluid had been found in the peritoneal cavity, and examination had proved it to consist mostly of bile mixed with serum. There was absolutely no jaundice of the skin or of the conjunctiva. The faces presented a clay color as in jaundice. It was evident that there had been a leakage of bile into the peritoneal cavity, and this was found to have come from the right hepatic duct close to the liver. In the retroperitoneal tissue posterior to and below the pancreas there was a large mass to which the greater curvature of the stomach and the transverse colon were adherent. On separating this adhesion, the pancreas was exposed, and a large cavity containing fluid and decomposed tissue of a green color opened. On section, the pancreas was normal. Close examination seemed to show peri-pancreatic fat necrosis. Whether the leakage in the right hepatic duct was to be explained on the score of injury or whether the necrosis of the fat proceeded along the adipose tissue in the hilus had not been determined. Laceration of the hepatic duct, he thought, must be very rare. The connection of traumatism with this case was very indefinite, and rested solely on the patient's statement that he had been run over.

Dr. Schultze also presented a specimen of cyst of the stomach as a pathological curiosity. It had been found in a woman about forty-five years of age, who had died from causes entirely independent of the stomach. The tumor projected about as much into the cavity of the stomach as on the peritoneal surface. It was situated about half-way between the greater and lesser curvature in the anterior part of the wall. On section, the tumor had been found to be embedded entirely in the layers of the muscularis. It resembled somewhat, in the gross, a cyst adenoma, but microscopical examination had failed to confirm this. It contained only large blood-vessels, connective tissue, and considerable areas of a substance resembling mucin.

Dr. Warren Coleman spoke of the case of hemorrhagic pancreatitis. The patient had entered Bellevue Hospital while the speaker was acting as substitute for Dr. W. G. Thompson. The patient had been seized a day or two previously with vomiting and intense pain in the epigastric region, darting toward the left side, though on admission to the hospital the pain was located chiefly in the right hypogastric region. The diagnosis of the physician who sent him to the hospital was intestinal obstruction. There was some tenderness on the right side, and two of the physicians who saw him thought there was rigidity of the muscles. The physical examination, however, was especially difficult, because of the thickness of the abdominal walls. The patient's temperature was 103° F., and the pulse rate 140–150. The characters of the pulse were very significant—rapid, small, feeble, and thready—a condition of heart action not consonant

with a temperature of 103° F. of only a few days' duration. These characters should have suggested pressure stimulation of the solar plexus, but did not at the time. In view of the patient's condition and the possibility of the existence of appendicitis, operative interference was decided upon, and the case transferred to the surgical division of the hospital.

Dr. George P. Biggs said that he had presented two similar cases to the society some years ago. The symptoms had been almost identical with those just emphasized by Dr. Coleman. Both had been diagnosticated as appendicitis, and one had been operated upon. The great rapidity and weakness of the pulse had been noted in one of these cases, and also the presence of marked dyspnœa.

Death from Ether Anæsthesia.—Dr. Harlow Brooks reported this case. The patient was a man thirty-six years of age, of good habits and free from syphilitic taint. He had received a compound fracture of the forearm which exposed both the wrist and elbow joints. When picked up he had not been in a condition of shock, and had been seen by a surgeon about three hours afterward, at which time there had been no urgent symptoms. The intention had been to amputate the arm the next morning. The man had passed a good night, and about eleven o'clock the following morning had been prepared for the operation. No lesion of the heart and lungs had been found, and the urinary examination had been negative. Squibb's ether had been used, and it had been taken without much struggling through what is known as the "butcher-sleeve cone." Plenty of air had been admitted with the ether, and the pulse had improved under the first inhalations of ether. While the arm was prepared the pulse flagged, and for this reason a hypodermic injection of strychnine and whiskey had been given. About twenty minutes after the beginning of the anæsthetic surgical anæsthesia had been reached, and the amputation was begun by an incision through the skin. The conjunctival reflex had disappeared at this time, the voluntary muscles were flacid, and there was every indication that the anæsthesia was complete. Just as the skin was incised, the respirations became noticeably slower, and there was some retching. A drachm of fresh ether was given, and soon the respirations became more natural. Five minutes after this the respirations suddenly ceased at the end of full inspiration, and the heart action ceased two or three minutes later. There was no cyanosis, but the anæsthetic was at once stopped, the throat cleared out, the epiglottis pulled forward, and artificial respiration performed. Strychnine and ether were given hypodermically at first, and the limbs were elevated. Air could be forced into the lungs, but there was no spontaneous respiration. Death probably occurred about eight minutes after the first symptoms of danger had appeared. About four ounces of ether had been used. A very careful autopsy had been made. There was no indication of previous disease. There was no injection of the blood-vessels of the respiratory tract in any part. The lungs were not congested or œdematous. At the autopsy, which was done about three hours after death, there was no odor of ether about the lungs. The ventricles of the heart were contracted as one would naturally expect from the mode of death, although the right auricle was moderately dilated. There was a small calcareous nodule on the posterior surface of the left-hand flap of the mitral valve. The valves of the right heart were normal. The heart muscle showed a moderate fibroid myocarditis, which was most marked in the papillary muscle of the mitral valves. The intima of the arch and the intima of the coronary arteries were the seat of quite extensive arteriosclerosis. This sclerosis stopped short with the arch of the aorta. All the smaller vessels of the body seemed to be normal, even on microscopical examination. The connective-tissue increase was of the adult form, and there was no indication that the condition was a progressive one. He had come to the conclusion that the condition was a functional arteriosclerosis occurring in an athlete's heart. The kidneys were like fibroid kidneys, yet on section this connective-tissue increase was not so apparent. There was only a slight connective-tissue increase of the adult form, and it was not progressive. The liver and all the other organs were normal. There was nothing distinctly abnormal in the central nervous system. A most noticeable thing in the nerve cells was an unusually plentiful deposit of coarse, brown pigment—a lesion not considered to be of special pathological significance. Careful examination of the ganglion cells by Nissl's method showed only slight and occasional degenerative lesions. The cells of the medulla were also normal. This careful examination precluded the possibility of an embolus or of discoverable lesion in the ganglion cells. The cause of death was apparently the result of the action of the anæsthetic upon the nerve cells; but, owing to the short duration of the etherization, it was hardly to be expected that any lesion would be produced which could be recognized after death by our present methods. Many surgeons were of the opinion that death from anæsthesia was most commonly the result of some obstruction in the respiratory passages, as for instance an accumulation of mucus. He had been surprised to find that most authorities agreed that the heart continued to beat for some time after respiration had ceased when death occurred during etherization. The case presented was one of death from respiratory failure from the action of the ether on the respiratory centre, or possibly by poisoning of the respiratory muscles. The case was most instructive as showing that death from ether anæsthesia might occur in a person apparently perfectly healthy, and when the conditions were most favorable for etherization and for resuscitation.

Dr. J. H. Larkin asked if fat emboli had been looked for in the brain and in the other organs. The association of the sudden death with a fracture seemed to make such a question pertinent.

Dr. Brooks said that the autopsy had been a complete one, and that a very careful and patient search had been made for fat emboli, but nothing of the kind had been found.

Dr. Schultze asked what had been the condition of the lymphatic system.

Dr. Brooks replied that there was no enlargement of the lymphatics, though it was looked for in every part of the body. The spleen was not much enlarged.

A Case of Tuberculous Endometritis, Salpingitis, and Peritonitis in an Infant of Twenty Months.—Dr. George P. Biggs reported this case. Five months prior to death a painful swelling had appeared on the right side of the abdomen, accompanied by constipation and gradual emaciation. On admission to the New York Hospital there was a large, tender mass in the right side of the abdomen, thought to be an inoperable tumor of the kidney. Death occurred about one month later. At the autopsy this tumor had been found to be a mass of fæces. The rest of the peritoneal cavity was protected by adhesions in which were many tubercles. An old perforation with rounded, smooth edges established free communication between the fecal cavity and the middle portion of the small intestine. There were a few characteristic tuberculous ulcers in the lower portion of the ileum. The mesenteric glands were enlarged and partially caseous. The involvement of the lungs was limited to a few recent miliary tubercles. The specimen presented consisted of the uterus and its appendages. The wall of the body of the uterus was 4 mm. in thickness, and its

inner 2 mm. was distinctly caseous and showed small areas of hemorrhage. The appendages were embedded in a mass of adhesions containing many tubercles. The Fallopian tubes were enlarged and contained caseous material. Only the surface of the ovaries was involved. The case was apparently one of primary intestinal tuberculosis with perforation and the formation a large fecal cavity, the process in the genital organs being secondary. The process in the uterus must have been a fairly old one, as shown by the extensive caseation.

A Case of Tuberculosis of the Bile Ducts and Solitary Tubercles of the Cerebrum.—Dr. Biggs also reported this case. The patient was a girl of three years. One year before death the child had had a sickness diagnosed by the attending physician as consumption. From this she apparently entirely recovered. Seven weeks before death the cough returned, and with it gradual loss of flesh. The physical signs were those of general bronchitis with scattered areas of broncho-pneumonia. The temperature did not go above 101.5° F. The day before death the patient had a convulsion with twitching of the entire left side of the body. At the autopsy, numerous tubercles were found in the kidneys, spleen, liver, lungs, and lymph nodes. The bronchi contained much muco-pus, and the lungs showed many areas of tuberculous broncho-pneumonia. In the brain there were two solitary tubercles, the larger of which measured 2.3 by 2 by 2 cm., and occupied the anterior portion of the left gyrus fornicatus. The smaller tubercle was in the left cuneate lobe. In addition to the distinct tubercles there were found throughout the liver many cysts 1 to 6 mm. in diametre, the contents of which were grumous material of greenish or yellow color. The gall bladder and larger bile ducts were normal. On microscopical examination the cyst walls showed typical tuberculous tissue. The presence of bile pigment and small remnants of mucous membrane proved the involvement of the bile ducts.

Dr. Northrup asked what was the condition of the bronchial lymph nodes in the first case.

Dr. Biggs replied that they were slightly enlarged, but were not tuberculous.

Dr. Northrup said that in two hundred cases of tuberculosis in infants and small children, collected by Dr. Bovaird and himself, there had been just three in which the evidence that the process was oldest in the mesenteric lymph nodes was manifest. He had presented a few specimens of tuberculous liver in infants in which it had been conspicuous that the bile ducts were very much thickened and dilated, and evidently the seat of tuberculosis. It did not seem to him that this class of lesions was unusual in infants.

A Case of Duodenal Ulcer of Embolic Origin.—Dr. Lewis A. Conner presented a specimen taken from a man of about forty-five years of age, who had sustained a traumatic amputation of the middle third of one leg. There was such serious infection that amputation at the knee had been done by Dr. Stimson at the Hudson Street Hospital. This wound had shown gaseous decomposition, but after severe infection lasting several days the man had recovered from the operation. After an interval of several days he had suddenly vomited enormous quantities of blood, and had died within a few hours. The termination of the case had been startling and most unexpected. At the autopsy a thrombosis of the entire length of the femoral vein had been discovered. This had been concealed during life by the dressing. There was also an embolus in a large branch of left pulmonary artery which, curiously enough, had given rise to no symptoms. In the duodenum immediately below the pyloric ring was a recent ulcer 3 cm. in diameter, and projecting from the centre of the base of the ulcer was a minute embolic plug completely filling the lumen of a small twig of the superior pancreatico-duodenal branch of the hepatic artery. The case was of unusual clinical interest, for the embolus, small enough to pass through the pulmonary capillaries, had found lodgment in the duodenal mucous membrane. The very large gastric hemorrhage seemed to him rather unusal in a case of duodenal ulcer. Again, this ulcer must have developed rather rapidly, because from the time of the accident to death was not more than three weeks. This ulcer must have formed and gone through the wall of the duodenum in the course of a few days. This was the second or third case of gastric or duodenal ulcer in which he had found an occluded artery in the base of the ulcer.

A Case of Large Carcinoma of the Prostate.—Dr. Conner also presented a soft carcinomatous tumor of the prostate taken from a man of seventy, who had died within a few hours after entering the hospital. He had presented symptoms of uræmia. A large, elastic tumor had been found in the right iliac region. At the autopsy the whole pelvis had been found filled with an encapsulated, lobulated elastic tumor, measuring 15 by 12 by 11 cm. The bladder had been lifted up out of the pelvis, and its mucous membrane was not involved in the growth. The rectum also had escaped. The kidneys were much diseased, and one ureter was dilated as a result of obstruction.

Dr. C. A. Herter said, with reference to thrombosed vessels in ulcers of the duodenum, that he did not think it at all uncommon to meet with hyaline thrombosis in vessels of ulcers of the stomach. He had seen these a number of times, and they seemed to play an important part in the formation of the ulcer.

Dr. I. Levin asked if there had been a complete obstruction of the urethra, and if the case was of uræmia from obstruction, or of coma connected with carcinoma.

Dr. Conner said that the kidneys showed that death had been unquestionably due to uræmia. There had been no retention of urine, and little or no obstruction in the urethra. The large mass in the right iliac fossa was an encapsulated metastasis. Metastatic growths were found along the retroperitoneal glands and in the bronchial lymph nodes.

A Case of Diabetic Coma.—Dr. C. A. Herter made some remarks on this case, which he had seen only at autopsy. The patient was a well-nourished woman about sixty years of age, who had entered the hospital in a stuporous state. She had soon become comatose. The urine contained a large amount of sugar. The case having been supposed to be one of diabetic coma, a quantity of sodium bicarbonate was infused into the venous system. The patient rallied slightly, but soon became comatose, and died within twenty-four hours. At the autopsy the brain showed considerable œdema. There was no thickening of the pia or any of the ordinary indications of chronic alcoholism. The lungs were normal. The heart muscle was pale. The liver weighed 1,617 gm. and was moderately fatty. The bile ducts were pervious. The pancreas was soft and very small, weighing only about half an ounce. The spleen was of medium size and appeared normal. The kidneys were large and pale, and the cortex was somewhat fatty. The suprarenals were normal. The urine in the bladder contained many granular and hyaline casts. The urine was examined with a view to ascertain whether all of the bases were neutralized by the known acids of the urine. If the bases were in excess, this excess must be due to the presence of organic acids in the urine, which had served to neutralize the bases. The blood and the cerebro-spinal fluid were also examined. The

simple atrophy of the pancreas was interesting. Of forty cases reported by Hansemann in which pancreatic disease coincided with diabetes, thirty-six were cases of simple atrophy of the pancreas. Dr. Herter said that his experience had been that simple atrophy was extremely common in diabetes. The proteids of the blood were removed by means of alcohol and the filtrate was treated with Fehling's solution. The result showed only a very small quantity of sugar. It had been thought for many years that the blood contained normally 0.1 to 0.3 per cent. of sugar, but these observations of Claude Bernard had been recently called in question, the reducing substance in the blood being thought to be not sugar but a substance called jecorin. It was probably an actual compound of dextrose with lecithin. If this theory were correct, it would explain why the blood normally contained no sugar, or only an exceedingly small percentage. The cerebro-spinal fluid showed more reducing substance than the blood, but it was not entirely clear that this substance was sugar. The urine contained 16.73 per cent. of the nitrogen of ammonia. This ammonia usually ran from 1 to 4 or 5 per cent. of the total nitrogen, varying somewhat with the diet. Such a high percentage of the nitrogen of ammonia, the urine not having undergone decomposition, indicated that the ammonia intended, under normal conditions, for synthesis with carbonic acid for the formation of urea, was diverted by the acids present, and was used for the neutralization of these acids. If this did not occur, death in coma would take place at a much earlier stage of diabetes. It was only when the quantity of acid was so great that the ammonia could not effect a neutralization that the acid took out the sodium, lessened the acidity of the blood, and led to coma. It was calculated that 10 gm. of oxybutyric acid and 33 gm. of sugar were excreted in twenty-four hours, thus making an enormous proportion of oxybutyric acid for the quantity of sugar present. In looking over other cases that he had studied, he found in one that there had been 20 per cent. nitrogen of ammonia and 25 gm. oxybutyric acid in twenty-four hours about one month before the patient went into coma, and the day before coma 21 per cent. of the nitrogen of ammonia and 23 gm. of oxybutyric acid. In a second case of coma the nitrogen of ammonia was 20.88 per cent. and the oxybutyric acid 27 gm. He had studied a few cases of diabetes in which coma had not occurred. One of these cases was now in Bellevue Hospital under Dr. Loomis' care. There were 27 per cent. of the nitrogen of ammonia and 24 gm. oxybutyric acid, and this had led him to give a bad prognosis, and on investigation he had found that the patient had been stuporous for the past few days. In another severe case there had been 16 gm. of oxybutyric acid and 20 per cent. of the nitrogen of ammonia. In still another case there had been 13 gm. of oxybutyric acid and 16 per cent. of nitrogen of ammonia. By changing the diet the nitrogen of ammonia had fallen to 11 per cent. and the oxybutyric acid to 8 gm. He had now under observation a case of diabetes that had lasted for fifteen years. At present there was about 5 per cent. of sugar in the urine. It contained 3.62 per cent. of nitrogen of ammonia and 1.8 gm. of oxybutyric acid. As there had been only a slight change in some months, the outlook was fairly good. Whenever the nitrogen of ammonia reached the neighborhood of 20 per cent. one must look out for coma. It was, however, a far less reliable index than the balancing of the acids and bases. This unreliability was particularly noticeable when the acid excreted was comparatively small in amount.

Dr. Conner asked if diacetic acid was no longer considered to be of importance in these cases.

Dr. Herter replied that he had said nothing about diacetic acid, because it was only one of the acids, and probably seldom amounted to more than 10 per cent. of the acids present. Unless the urine was very fresh it was impossible to study this acid. He believed beta-oxybutyric acid was the chief acid.

Primary Carcinoma of the Lung with Multiple Metastases.—Dr. E. Hodenpyl presented specimens from this case. The patient was a man fifty-five years old who had been previously well. He had been ill for five months with cough, dyspnœa, and pain in the left chest before coming under observation. There was dulness over the upper lobe of the left lung with very distant bronchial breathing and absence of voice and vocal fremitus. Puncture of the pleural cavity and examination of the sputum had proved negative. A diagnosis of probable tumor of the lung was made. The man had had two or three slight hæmoptyses. During the last month he had become delirious. At the autopsy a new growth had been found in the left lung. The costal pleura on that side was very greatly thickened, though not involved in the new growth. There was also a fairly acute pericarditis. The suprarenal capsules had been replaced by a new growth, and the pancreas was studded with large nodules. There was a new growth in the right occipital lobe of the brain. The other lung was entirely normal. Microscopical examination showed the growth to be a large alveolar carcinoma.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 12, 1901:

	Cases.	Deaths.
Tuberculosis	249	182
Typhoid fever	56	13
Scarlet fever	270	12
Measles	99	2
Diphtheria and croup	277	69
Smallpox	17	3

Tea and Coffee as a Cause of Insomnia.—Sir James Sawyer, Birmingham, Eng., lecturing recently on insomnia, said: "The effects of the consumption of tea and coffee in causing sleeplessness are well known. This effect is so obvious that patients usually remedy it for themselves. As you well know, tea in the form of an infusion or of a decoction is generally used in civilized countries as the daily beverage of the people. Tea leaves contain an alkaloid which has been called theine, and coffee seeds contain caffeine, and theine and caffeine have been shown to be identical, and both these leaves and these seeds contain only principles. With regard to tea what may be called its physical action appears to depend upon the joint action of its theine and of the volatile substance which tea leaves contain. What is called green tea is produced by drying the fresh leaves on a heated iron plate, until they become shrivelled; while black tea is manufactured by placing the leaves in heaps and allowing them so to lie while they undergo a kind of fermentation, after which they are dried. Green tea and black tea are powerful cerebral stimulants, exciting the mental faculties and the cerebral circulation, and tending to prevent sleep. Coffee, too, is a cerebral stimulant and antisoporific. It is sometimes used in need for these properties to counteract the effects of opium and its derivatives, and of other narcotic poisons. Some

people are extremely susceptible to the sleep-preventing effects of tea and coffee, others by use do not feel such effects, even when considerable quantities of the beverages are consumed. In all cases of bad sleeping you should make sure that tea or coffee is not taken to excess near bedtime."

The Neurotic Form of Enuresis.—This according to Amat (*Bull. gén. de thér.*, November 8, 1899) has several varieties and demands distinct treatment. In the first variety the vesical muscular fibres are too sensitive to distention; and although this is kept in check during the day by the will it leads to incontinence as soon as the patient drops asleep. The drugs indicated for the relief of this condition are the bromides, chloral, opium, belladonna, and antipyrin. In the second variety there is proper æsthesia of the vesical and urethral mucous membrane, a condition manifested by the passage of a catheter, and which is best treated by the ammonio-sulphate of copper. In a third variety the vesical sphincter is not irritable but weak, as shown by the ease with which a catheter passes through the membranous portion of the urethra. For the relief of this condition strychnine, rhus aromaticus, and more especially electricity are indicated.

Formaldehyde Gas for Disinfecting Books in Libraries.—For some time the belief has been current, doubtless not without good foundation, that diseases are contracted by handling books in public, which have become infected with the germs of some disease. The New Jersey authorities have been the first to take preventive steps, owing to a case of scarlet fever, which had been shown to be transmitted by the agency of a book in a travelling-library. Professor Mitchell, of the New Jersey State board of health, has been conducting a number of experiments with formaldehyde gas, using kindergarten toys and public school books, and so far it has been found the surest destroyer of microbes, working quickly and effectively. This has been demonstrated to the satisfaction of the experimenters, but the experiments are being continued to discover what is the least amount of the formaldehyde gas that can safely be used, not only to kill the germs, but to make the books germ-proof, at least for a time.

Mental Disease and Toxæmia.—Sir S. Dyce Duckworth lecturing on the above subject says: "Mental health must surely be dependent on the integrity of the brain cells and neurons. Psychic endowment, no less than ordinary nerve energy, requires a normal condition of the machinery for its functions. The nuclei of the myriad cells, as physiological centres, their plasmic environments, the processes of their cell, their fibres, and their collaterals must be intact, and the subtle metabolism at once securing nutrition and dispensing energy may not be disturbed or prevented without manifest disturbance of psychic and ordinary nervous rhythm." Sir Dyce Duckworth then went on to describe the various phases of mental disorder which depend on the toxæmic states, and said that the origin of the toxins by which they are caused is at least threefold. They may be said to be generated within the body (auto-intoxicants) or by the malign working of microbes introduced from without, or by impregnation with poisons of various kinds, including those resulting from habits of alcoholism, chloralism, cocainism, and morphinism. In the majority of cases of insanity, probably, there is a hereditary predisposition to the disorder, but in some cases a previously normal brain may be so damaged by toxic influences as to a manifest aberration, as may be seen in the varied forms of uræmia, in the autotoxy of diabetic coma, or in that which depends on acute atrophy of the liver. The effects of these auto-intoxications are as certain as those of poisons taken by the mouth or hypodermically, and the chemical functions of the brain cell are disordered in precisely the same manner.—*Hospital.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended January 11, 1901:

		Cases.	Deaths.
Smallpox—United States.			
Alabama, Girard	December 31st	*	
Phœnix	December 31st	*

EARLY DIAGNOSIS OF MAMMARY TUMORS.[1]

By GEORGE F. SHRADY, M.D.,

NEW YORK.

The necessity for making an early and accurate diagnosis of a suspected malignant tumor cannot be too strongly urged. In advanced cases of carcinoma there need be no question as to positiveness regarding their nature, but then, oftentimes, the suggested remedy is too late for hopeful application. It is for lack of appreciation of the initiatory signs of malignancy in a given growth that the general practitioner, who is first consulted, postpones his opportunity until he is forced to see that he has been misled from the start. Particularly is this condition of affairs manifest in the frequently occurring tumors of the breast which, in doubtful conditions, present so many puzzling questions for ready answers.

In the effort to give a somewhat practical turn to a part of the subject, to which more attention may be directed than is ordinarily given, I purpose to discuss partly on the basis of personal experience some of the debatable points which so frequently stand between positive opinions regarding benignancy on the one hand and malignancy on the other. While we are forced to admit, on general principles, that all mammary tumors are bad, and that the majority of apparently harmless ones turn out disastrously, there is still a reasonable number that are innocent in character from beginning to end. The greatest question of all in this discussion hinges upon the possibility of drawing the dividing line in its proper place. This is as important in regard to the earliest possible operation that can be made in a doubtful and threatening growth, as in those fewer cases in which the patient can be assured of safety without such radical treatment. We thus span also the border line between the extremes of positive declaration that an operation may be unnecessary on one hand or useless on the other. When the most experienced surgeons are liable at times to err in this particular, it proves the more that the general practitioner should not trust to ordinary generalizations in offering opinions. Although it is a good rule to refer all morbid growths to experts, he can often, by appreciating certain salient clinical features, avoid positive contradiction in the final verdict, or, at least, save himself the mortification of being charged with neglect in allowing malignancy to entrench itself under his very eye.

If we start with the study of a well-developed cancer of the breast, we can perhaps obtain a working basis for comparison with similar growths minus the malignancy. There are the growing stony tumor embedded in the gland substance, the puckered adherent skin, the characteristic orange-peel look of the latter, the retracted nipple, and the enlarged axillary glands. Every one should know the nature of such a disease when fully developed so soon as he sees it. But it is the condition short of this in one particular or another, that causes the careful man to stop and think. There is nothing to help his conclusion beyond the growth itself. In incipient carcinoma there is no diathesis present that can give him a desired clew, as all varieties of temperament and of physique are on a common plane of predisposition. It is the absence of all the cardinal marks of cancer save tumor that may often argue for benignancy. Upon a decision pro or con depends the saving of the breast by simple removal of the growth or cutting away breast, axillary glands, and all contiguous tissue. If we preserve the mamma when it can be done, everything is saved for patient and surgeon. It is perfectly legitimate to aim at such a possibility, although it is never allowable to shut our eyes to sterner facts in other directions.

There is, of course, much to influence us in the diagnostic way in reference to age, although all tumors in old women are not necessarily malignant. The fact is exceptional, it is true, but the interest in the present study is precisely in such directions. One patient of mine dying at seventy-five years of renal trouble carried a fibro-glandular tumor for thirty years, the growth undergoing no degenerative change during that period. Similar cases have occurred in the practice of others.

Chronic circumscribed mastitis, although it takes its place in the list of innocent infiltrations, is often mistaken by the novice for a more serious trouble, but generally speaking its distinctive marks can be readily recognized. It is the only form of so-styled tumor which does not respond to the tumor test. There is an increase of substance; it is irregular, nodular, diffusive, often multiple, but conveys no sense of projection and condensation to the gentle pressure of the outspread hand upon the breast surface. This fact may be explained, in part at least, on the score that the conditions of difference between the sound and the affected parts are those of degree rather than of kind. Then, again, separate involvement of different areas of breast tissue is never the rule in cancer. Curiously enough, grasping the affected parts laterally gives a distinct impression of more or less extensively diffused and increased hardness, which is always the cause of great anxiety to the patient when the real cause of the phenomenon cannot be reasonably explained. A proper diagnosis generally depends upon the fact whether or not the induration is more or less isolated and tends to increase. In the former case there is always a suspicion of incipient malignancy, especially if the swelling increases in a patient who has passed the climacteric. Exceptions to this rule are, however, generally allowable when the infiltration is centred around the site of an old abscess scar or a discharging breast sinus. It is in these single and more or less circumscribed deposits that cancer is said to develop so frequently. This fact would appear to give color to the probability that, instead of malignancy having been induced by mere interstitial changes, it was such from the beginning. If the contrary view obtained, that a confessedly innocent infiltration always invites cancerous deposit, there would be no law against a simultaneous malignant invasion of the separate indurations having similar conditions of receptivity. I

[1] Read at the meeting of the Practitioners' Society, January 4, 1901.

have never seen cancer develop in a breast in which distinctly isolated points of induration have existed, although such occurrences have been noted by others. The latter fact, however, is no argument against the supposition that the particular malignant growth may be entirely independent of a benign growth in the same or other breast.

Another point worthy of note in this connection is that mastitis, when quiescent for months, seldom takes a distinct neoplastic tendency afterward. I can recollect no exception to this rule in my experience. Clinically speaking, simple chronic interstitial mastitis as such has not shown any disposition, so far as my observation has gone, to convert itself into carcinoma. It has always seemed to me that it should be one thing or the other from the very inception of the trouble.

As there are no clinical means of distinguishing a fresh patch of mastitis from a commencing carcinoma, the only way to clear up doubts in either direction is to study the case carefully and note whether or not there is any progressive development of the affected part. "In no branch of morbid pathology," says Sheild, "are mistakes more commonly committed by too confident observers than in this," and he further states that in doubtful cases even the microscope may fail to draw the line between actual benignancy and commencing malignancy, especially when the epithelium of the tubules or acini shows a disposition to cell proliferation.

It is a pity that we have no means of prognosticating such cases on the basis of what may be called a cancerous predisposition. Heredity does not help us much in this direct line of inquiry, although on general principles it should give us a reasonable hope of answering a difficult question. The theory of parasitic origin is far from being substantiated. The only arguments in its favor are those of analogy. The disease is not communicable. So far as we know at present, it originates locally in isolated areas, and certain collections of epithelial cells are seized with an insanity of proliferation which defies all ordinary laws of control. Many authors ascribe this proclivity to purely protoplasmic influences, as if in our present state of knowledge that could mean anything more than a virtual admission of our inability to explain anything. It is merely another way of admitting the embryonal origin of the process which nevertheless is involved in like obscurity as to relations of cause and effect. Thus far we know merely that embryonal cells have multiplying powers of their own, their malignancy being in proportion to the low scale of their development. It is not, however, the purpose of this paper to discuss questions of pathology except in an incidental way so far as they may explain some of the difficulties in early diagnosis.

Adenomatous tumors of the breast, occurring as they do mostly in younger women, are typically benignant growths. Being more condensed and circumscribed than the contiguous mammary tissue, they always respond to the tumor test. Although they are sometimes deeply and firmly incorporated with the gland substance, they are usually quite movable under smooth and healthy tissue. This ofttimes multiple character is also significant of their comparative harmlessness, as well as their ready and painful responsiveness to menstrual impressions, and above all their very slow growth. While the presence of these negative features regarding the suspicion of malignancy are significant enough in typical cases, there is in the doubtful ones, in which leading signs are wanting, often much difficulty in making positive diagnoses. This condition applies most particularly to the more or less embedded and fixed varieties. Often a definite opinion in such cases hinges upon the demonstration of the disconnection of the tumor with the gland proper. Although this may not always be possible, I am convinced that it can be done in most instances by firmly steadying the breast and by making efforts to move the growth independently in different lateral planes. Even in the stalked and embedded fibro-adenomata there are generally one or more directions in which limited mobility can be obtained when the growth can be fairly grasped and isolated. It can easily be seen that this diagnostic sign is not common either to cystic growths or to chronic mammary infiltrations and certainly not to carcinomatous deposits. The only exceptions that occur to me are those of lipoma and enchondroma, which, besides being very rare, have other characteristics not easily escaping ordinary observation.

The fibro-neuromatous tumors, which for benignancy may be classed with the adenomata, are not of common occurrence, are generally of small size, have severe pain as a leading element, and, so far as I know to the contrary, are always superficial and very freely movable under healthy skin. It would hardly be conceived that any error in diagnosis should be made in such cases, although I call to mind two instances in which amputation of the breast was resorted to for supposed cancer.

It is with the likewise embedded cystic tumors, however, that the greatest difficulties in diagnosis are often encountered. While it must be admitted that the only absolute test of correct opinion is the aspirating-needle and the withdrawal of fluid, there are other points to be considered in connection with physical signs which if not equally conclusive are in their way strongly corroborative of suspected conditions. With a typical retention cyst, it is easy to understand why it should have a more or less globular form and why pressure on its most prominent projection should give a peculiar and significantly elastic feel. The latter symptom, apart from the aspiration, is a characteristic and extremely valuable diagnostic sign. It is never obtained, so far as I can attest, by other than this direct form of intercepted pressure. Sometimes it is entirely absent, especially when the growth is very deeply situated, and occasionally under such conditions even aspiration fails to find fluid. Almost every surgeon of large experience has met with dry taps under such circumstances. In the discussion of Dr. Bull's paper on cystic tumors of the breast, recently held before this society, such cases were related. Dr. McBurney gave instances in point. In one he was so sure of carcinoma that aspiration was not deemed necessary, and in another a careful preliminary exploration with the needle was without result. I have had a like experience in similar cases.

Why aspiration should sometimes fail it is somewhat difficult to explain. Probably in certain cases even a good-sized needle may be plugged by a punched-out portion of a thick cyst wall or clogged by densely viscid fluid, and in others the cyst itself may be simply transfixed or skirted by a too deeply plunged needle.

Taking chances, however, of occasional failure in the procedure mentioned, it is not likely that all the other significant signs of cyst are absent. In one instance of "dry tap" the marked globular shape of the tumor when the patient was under ether very effectually confirmed my previous suspicion of its real nature.

It is well to recollect in this connection that a discharge of yellow fluid from the nipple is a very important item in cystic disease, as is also the occasional rapid disappearance of the swelling. This is probably due to a more or less direct communication with adjacent ducts which when obstructed from any cause may give opportunity for a reaccumulation of fluid. Sheild is of the opinion that "sudden alteration in

volume of a tumor of the breast is always a sign of cystic formation." I have noted two instances of disappearance of retention cysts, in one of which it was clearly due to rupture of the wall by direct injury to the part. It need not be mentioned that all cysts are not necessarily benign in character. We meet with them in the villous and soft forms of cancer, as well as in sarcoma, and occasionally an ordinary retention cyst will develop malignant degeneration in the inner surface or in the substance of its walls. Under such circumstances the fluid is almost invariably either deeply tinged with blood or contains decomposing or broken-down tissue material. Encountering one such case years ago has influenced me in advising the resection of the cyst wall in all doubtful cases, rather than the simpler and more generally practised method of aspiration.

Sarcomata of the breast, comparatively infrequent in themselves, are very apt in one way or another to compass many of the physical characters of the benign growths. In their inception they may closely resemble embedded adenomata in firmness, shape, and outline; the only elements of suspicious malignancy being their composite character, rapid growth, multiple cyst formation, and their irregular and boggy softening. In the latter respect they resemble soft carcinomata, although these forms of cancer usually break down in their centres only. It would hardly be supposed that these softened areas would be mistaken for single or multiple abscesses, although they are known to have been freely incised on such a presumption. Palpation, as a rule, does not give any distinct sense of fluctuation, but rather a mushy and yielding feel that is quite characteristic when once it is duly appreciated. Then, again, aspiration quickly discloses the true nature of the pathological process of neoplastic changes.

When we admit the fact on one hand of the breast having been extirpated for cancer when a mere chronic abscess existed, and on the other hand of acute suppurating carcinoma having been allowed to go to the bad without operative interference, we are impressed with the necessity of more accurate study of their differentiating conditions. It is generally admitted that in obscure cases of abscess the diagnosis is often extremely difficult. The symptom of fluctuation which is associated with suppuration is in the deep abscesses often entirely absent. The expansive and irregular infiltration of the tumor usually gives the impression of another and more significant process. The persistence of the tumescence without elevation of temperature or marked tenderness on pressure are suspicious circumstances of grave import, especially in older women who may be past the climacteric period. Even the pitting of the overlying skin by finger pressure—the pathognomonic sign of suppuration—may be wanting, as well as the abrasion or crack in the nipple which so commonly offers an entrance for the primary infection. As a rule, however, there is always more or less throbbing pain, and the skin of the affected part is more or less œdematous. Of course, the absolute necessity of aspiration in order to clear up all suspicions of imprisoned pus need not be urged.

In studying the question from the standpoint of excluding malignancy we may also view the situation in a more or less practical way by noting such inclusive phenomena as may justly arouse suspicions in opposite directions. It is then that we can duly appreciate the true significance of those initiative signs which give us our first warnings of the gravity of any given case. Among these I would class the dimpling of the breast, often the first thing noticed by the patient, as perhaps the most significant of all the early physical phenomena of cancer. In the large majority of cases it is always present and when found is in itself almost pathognomonic. The nipple at this stage is not involved, as a rule, nor is the overlying skin otherwise implicated in the usually puckered way, as it is later on. Not very infrequently this indentation of the skin due to the involvement of the fibrous processes, which radiate in different directions of the healthy gland, is restricted to the nipple, thus accounting for retraction of that organ as an exceptionally early symptom. The depth of the growth is seemingly no bar to the development of the dimple in question, as in many cancers which have a submammary origin it is very plainly manifested.

Regarding the tumor test in these cases it may be said in general terms that almost invariably it can be clearly demonstrated by placing the patient in the recumbent position and stroking the breast with the flat of the hand. From personal experience I am able to state that I have never yet failed to detect a carcinomatous tumor in any portion of the breast when this important means of diagnosis was carefully applied.

The hard fixed tumor as associated with the condition named and the occasionally darting pains are, in my experience, the earliest possible signs of cancer that are usually called to the notice of the general practitioner by the anxious patient. The latter, as a rule, generally discovers them very accidentally. She comes to him for advice and comfort, and he very often gives both, to her utter detriment. Neither party to the contract wishes to believe in grave outlooks, and both are content merely to watch and wait for future developments. The results are such as are often seen by the surgeon when on his first consultation he recognizes the widespread character of the disease and its comparative hopelessness of cure by operation.

Enlarged axillary glands, valuable as are their indications of cancerous infiltrations, are not in themselves of special or absolute value in a strictly diagnostic sense, inasmuch as we see them in chronic mastitis, abscess, chancre of nipple, simple eczema of the latter organ, and even in adenomata and inflamed cysts. Generally, however, in advanced cases of carcinoma, when the nodules are significantly corroborative elements of diagnosis, there is not that degree of sensitiveness on handling that is noted with the more innocent involvement of these parts. Besides, they do not give the impression of such distinct hardness, fixidity, and chain-like arrangement as in malignant cases.

Although this condition cannot, by itself, be classed among the first signs of malignancy, the deeper portions of the axilla are usually very early involved, notwithstanding the enlarged glands may not be felt at the time. In fact, we have no means of proving how soon the infiltration may take place in any given instance. Under some circumstances it would appear to be an almost simultaneous involvement with that of the gland itself.

This, after all that can be said on the subject on hand, brings us to the true moral of our story. It is re-emphasizing the necessity of early and accurate diagnosis in all cases of breast tumors. Mammary growths, as a class, can never be trusted. The weight of evidence is so strongly on the side of malignancy, threatened or pronounced, that no conscientious practitioner can afford to have any doubts as to the responsibilities he should assume. There is hardly a "simple tumor," so called, which, when discovered in the breast, may not eventually become malignant. The man who takes the chance of an exception to this rule must of necessity be very sure of his ground. On such a possibility all rational and timely treatment necessarily depends. No question of diagnosis in any other disease has a more practical bearing on ultimate results. Fully ninety per cent. of

breast tumors in older women are probably malignant, and the remaining ten per cent. are very objectionable tenants. A mammary neoplasm is bad company, no matter how we may argue to the contrary. It is the leaven in the lump which may at any time assert itself.

If it were necessary to emphasize any further the necessity for accurate diagnosis in each individual case, it should be added that the surgeon who is to operate should, above all others, place himself beyond the chance of possible error. The only absolutely sure way to do this is by an exploratory examination of every tumor before its actual extirpation is attempted. This is the rule with every careful operator. No matter how plain the case may appear to be, there is no argument against being doubly sure. In one instance, when no doubt as to correctness of diagnosis seemed possible, when the stony fixed tumor was there, when the skin was dimpled, when the axillary glands were enlarged, and when even previous aspiration was a cheat and a snare, I have happily by such means saved a condemned breast by the simple enucleation of an inflamed, thickly walled, and deeply embedded cyst.

The strongest side of the argument for safety is the removal of all growths, whether in young or old. It is only a question of saving the breast in the case of benign tumors, and of sacrificing the entire organ and its varied lymphatic connections on the other. Even in adenomata there are the best of reasons for this course, considering the oftentimes great suffering during the parturient and lactating periods, and the additional fact that the subsequent engrafting of malignancy is by no means an absolute impossibility. No tumor of the breast can be considered a trivial affair. The first thought of the victim is that of probable cancer, and in the great majority of instances, with age on the side of the argument, her suspicion is reasonably well founded. The main obstacle to the definite settlement of the question is the family physician himself, who too often calms reasonable fears and postpones judgment until the disease entrenches itself beyond the hope of its radical and absolute conquest. Thus the chance of the earliest possible diagnosis is denied the anxious patient and the first irretrievable step is taken toward an utterly hopeless prognosis.

8 East Sixty-sixth Street.

SOME FURTHER WORK ON THE MOSQUITO-MALARIA THEORY, WITH SPECIAL REFERENCE TO CONDITIONS AROUND NEW YORK.[1]

By WILLIAM N. BERKELEY, A.B., M.D.,

ATTENDING PHYSICIAN, GOOD SAMARITAN DISPENSARY; LABORATORY ASSISTANT, PRESBYTERIAN HOSPITAL.

The capacity of mosquitos (or "gnats") of the genus Anopheles to convey the parasites of malaria from man to man is now conceded. The history of the discovery and the biology of the process have been written and rewritten. The object of this paper is not to reiterate these well-known facts, but to describe some fragmentary work of my own during the past season (in so far as the results of it bear usefully on the facts already known), and to comment on the conditions peculiar to the environment of New York. My paper will touch on (1) the local species of Anopheles and their natural history. (2) Inoculation experiments. (3) The incubation period of malaria. (4) Prophylaxis and eradication of the malaria endemic in our own locality.

First. The general biology of the American Anopheles has been already admirably set forth in an exhaustive publication by the Entomologist of the Department of Agriculture, Dr. L. O. Howard.[1] This bulletin—No. 25, New Series—left nothing of importance to be added up to the date of its issue last August.

Of the three species of Anopheles native to North America and described in this pamphlet, I have found two around New York, A. quadrimaculatus Wiedemann and A. punctipennis Say.

As regards the names, A. quadrimaculatus is the same mosquito, apparently, as A. maculipennis Meigen and A. claviger Fabricius. Ficalbi,[2] whose devotion to the scientific study of mosquitos has recently produced two exhaustive and useful volumes, appears to make out a fair claim to priority for the name claviger given by Fabricius in 1805. It would save confusion to allow this claim at once and drop the wasteful and ridiculous excess of names we are using. As a physician, however, I have no part or lot in a controversy about zoological names.

The structural differences between Culex and Anopheles should now be familiar everywhere. A good working rule is that Anopheles has palpi as long as the proboscis, and (what is perfectly true for our local species) spotted wings. As regards the angle made by the body of the resting insect with the wall, I have given the matter some original study, and I believe that a degree of inclination is generally present, but not, in our species, so marked as has been claimed. When resting on a perpendicular wall Anopheles will often incline its body at an angle of 15° or 20° with the wall, but more than 45° is rare, particularly with A. quadrimaculatus. A. punctipennis hangs, as I have observed it, at a somewhat greater angle than A. quadrimaculatus; but, unfortunately, certain of the Culex species, particularly when well-fed and hanging from ceilings, sometimes assume the same posture, and relying on this sign alone, I have not infrequently caught Culex for Anopheles, discovering the error only when I had a bright enough light to see the palpi or wings.

Anopheles was never found without Culex, oftenest C. pungens; rarely C. tæniorhyncus. A. punctipennis is abundant in certain parts of Bronx Borough (particularly Jerome Park). A. quadrimaculatus appears to be universally distributed in our suburbs. Since I learned how and where to look for it, I have found it nearly coextensive with all the cases of fresh malaria that I had leisure to go and look into. It was present in such widely separated places as Passaic, N. J., Tuxedo, N. Y., Fordham, and Jerome Park. Dr. Robert T. Morris informs me that he observed it in Mt. Vernon, November 18, 1899; and many beautiful specimens, both male and female, were kindly sent me all the way from Easthampton, Long Island, by Dr. Fred. P. Solley.

In respect of Easthampton it ought to be at once stated, on Dr. Solley's authority, that till last summer no native malaria has been known there for many summers past, in spite of the large number of malarial mosquitos. This admits of two explanations: one, that no malarial case has been recently imported there to start an infection among the mosquitos; another, that the nights are cold. The residents of the town are said to sleep under blankets all summer; and if this is so, the night temperature must be considerably below the minimum (77° F.) at which the malarial

[1] Read before the Section on Medicine, New York Academy of Medicine, January 15, 1901.

[1] Prof. B. Grassi's recent book, "Studi di un Zoologo sulla Malaria," is said to be equally valuable for the Italian species. I have seen only reviews of it. Ficalbi's "Revisione Systematica delle Culicidæ Europee," Firenze, 1896, is a work of vast scope, covering the whole European Culicidæ. Papers by Dr. Albert Woldert in the Journal of the Am. Med. Assoc., 1900, are also of great value in practical work.

[2] Ficalbi: "Venti Specie di Zanzare (Culicidæ) Italiane," Firenze, 1899, p. 93.

bodies are believed to develop in the stomach of the mosquito.[1]

The same conditions have been often observed in Italy,[2] and in the East Indies.[3]

It ought to be mentioned also in fairness that I could in three cases find no Anopheles either in houses or vicinities where fresh cases of chills and fever had recently developed. Two of these cases were kindly shown me by Dr. N. B. Van Etten, of Tremont, and a third by Dr. F. W. Shipman, of Mt. Vernon. Two afternoons were spent in trying to discover adult or larval Anopheles in or around the houses in question, but neither could be found. Newly made streets were near at hand, however, and the up-turned and ill-drained soil could have easily caused rain-pools of long enough duration to hatch one set of eggs. Moreover, judging by the accounts of the workers on the British Malaria Expedition to West Africa, who usually found Anopheles absent from houses in the daytime, my success in all the other cases was hardly to have been looked for.

As to *habitat*, Anopheles was found always in buildings, oftenest on the walls and ceilings of recently used bedrooms, and far most abundantly in the foul and ill-ventilated bedrooms of the poor—among whom, it is needless to say, malaria works its greatest mischief. The house females were usually gorged with blood, and sluggish enough to be easily caught. They were numerous in old-fashioned latrines.

For weeks and weeks I have looked for the adults out of doors—along the margins of pools, in damp rushes, and under trees near houses where they were numerous. They were never to be found—having apparently nothing of the daytime voracity that makes Culex such an intolerable pest. The males I found were caught in houses also. They were usually present in the proportion of about one to twenty females—sometimes absent entirely for several days during those parts of the day when I could look for them.

How early in our spring the females begin to bite is uncertain; for those that have found a warm berth during the winter in a tight cellar or a greenhouse the early March sunshine is probably stimulus enough. The following case is presumptive evidence.

A. N——, forty-nine years old, a shrewd old German gardener, from Larchmont-on-the-Sound; he was positive he had not had a day's illness with chills and fever for eight years. On the 16th of last March he was taken with a severe chill, and a few days later I found characteristic tertian parasites in his blood in vast numbers. My theory is that he had been stung by mosquitos in his bedroom or greenhouse about two weeks before his first chill, let us say March 1st. Of course, if any one disputes this and thinks the attack was a relapse, I have nothing to allege in answer except the patient's own history.

An immense number of these cases in early spring are undoubtedly "hold-overs" from the year previous. Indeed, so far as I have examined the literature, there is very scanty evidence that Anopheles infected in the fall retains its parasites in a viable condition through the winter. Gosio[4] and many other Italian observers have not found a true case of primary infection before June 15th, when new-born Anopheles had had time to develop parasites from the relapsing cases of the year previous.

As to how late in the fall Anopheles is still to be found, Dr. Morris' observation has just been quoted. I found them still in one house in the Bronx on November 6th—one or two males also. On Christmas day, in a draughty, cold underground cellar (temperature about 40° F.) in the yard of the same house, I caught a dozen or more—all females—mostly punctipennis, a few quadrimaculatus. They were in complete hibernation, and had to be knocked from the wall as though dead, but in a glass tube under the warmth of the hand they revived. I looked in vain on that day for males. So far as I know, the hypothesis of the Italian workers, that only fertilized females survive the winter, is true.[1] On January 13, 1901, in the same cellar females were still numerous—no males.

I append here some notes on a large batch of Anopheles quadrimaculatus reared from the egg in the city last August. Artificial conditions vary so from the natural that such data are only of relative value. These I give for what they are worth. Gravid females were confined in a wine bottle with a little faucet water, Saturday, 11th August. Larvæ were found active Tuesday the 14th. On the evening of August 29th or morning of the 30th, the first pupa appeared, and on the evening of the 31st, the first imago (male). The second pupa (31st August) died; the third pupa appeared on the 2d of September, A.M.; the third imago on the 4th of September, A.M.

The weather for the most of August was damp and intensely hot. The larvæ received nothing to eat for the first few days. In this time they fairly gutted the dead bodies of several adult females accidentally left in the dish with them. They afterward fed well on green ooze (algæ) and almost any kind of slime from stagnant frog-ponds.

The time from egg to adult thus observed is certainly not more than nineteen days. Better food and care of the larvæ would doubtless have further shortened the period. In natural pools in midsummer with us, the eggs probably develop fully in twelve to fifteen days. For Italy and the tropics the interval is doubtless further shortened, though breeding experiments described by Ficalbi (*l.c.*) were slower than mine.

A curious fact in the dietology of Culex is that, particularly on Long Island and the Connecticut shore, vast swarms of male insects appear around dwellings at times and completely cover a portico or fill a room or an out-house. These are called by the laity "fuzz-bills," and are well known to be perfectly harmless, never biting. I have not been able to find out that this has ever been noticed with males of the genus Anopheles.

Second. Inoculation experiments. As to the several species of malarial parasite endemic in and around New York, some useful observations have been published by Dr. F. P. Solley (Presbyterian Hospital Reports, 1898). Dr. Solley's account is incomplete in respect of the æstivo-autumnal infections, which are by no means rare. Among the laborers on the Jerome Park reservoir alone, I found a houseful of them.[2] The tertian cases are the commonest, the quartans being so rare among us that I have not been able to satisfy myself of a single authentic attack. As compared with the tropical cases all our local fevers are benign. They are, however, often prostrating, and usually hard to cure, relapsing readily if the remedies are too soon laid by, and often reducing strong men to an extremity of wretchedness and anæmia. The crescents are usually uninfluenced by quinine.

The new classifications of the malarial parasite promise to work much improvement in our knowledge; they are, however, as yet unsettled, and in this paper

[1] R. Koch: Deutsche med. Woch., September, 1899; Celli: Supp al Policlinico, No. 48, 1900. The latter does not yet consider the minimal temperature definitely settled.

[2] Celli: *L.c.*

[3] R Koch: Deutsche med. Woch., 1900.

[4] Il Policlinico, April and May, 1900.

[1] The wonder is that any of them can survive the intensity of northern winters. The Rev. Gilbert White was gently urging this question over a century ago: "Why the juices in the small bodies and smaller limbs of such minute beings are not frozen, is a matter of curious inquiry."—"Natural History of Selborne."

[2] See also Dr. G. L. Peabody, MEDICAL RECORD, January 5, 1901.

I have used only the old terms. The next Zoological Congress will perhaps agree upon a single set of names.

The main aim of my inoculation work has been to ascertain what species of our native Anopheles carry the specific germs of the several forms of our native malaria. The work has been prosecuted among many interruptions, and I have had to attend to every detail of it in person, being without an assistant. Very modest claims are made for its value. It is recounted principally in the hope that other men may be induced to take up the questions raised, and assist in bringing them to a satisfactory conclusion.

For avoidance of error the following rules were adopted. No mosquitos should be used except those that had been reared from the egg or that had been confined long enough after being at large to give ample time for earlier accidental infections from man, birds, or other animals, to disappear as coccidium bodies from the stomach wall. Inoculated mosquitos were incubated at a temperature of 80°–85° F., and fed when necessary on cane-sugar solution. They were found to live most quietly in partly lighted incubators, and were confined in large test-tubes an inch in diameter, stopped with absorbent cotton. The sugar solution was supplied on small swabs, the insect being thus much less likely to get legs or wings stuck while feeding. Dissections were mostly made on the third to the fifth day after the bite. Both the local species were used. I succeeded after repeated experiments in inoculating A. quadrimaculatus with the tertian parasite. Three bites gotten from a man with a moderate number of crescents all failed. Dr. W. S. Thayer has already announced successful inoculations of A. quadrimaculatus with tertian and crescent parasites at Johns Hopkins Hospital.[1]—Of my stock of home-bred mosquitos an immense majority of those finally reaching the imago stage were males; of the females that would bite none "took."

With the first cold nights in the early fall the number of available hospital patients fell off rapidly, and it became much harder, even after a week's starvation, to make the mosquitos bite. Further work had, therefore, to be put off till next summer.

Coccidium bodies and infected glands were very hard to find in gorged mosquitos caught in rooms where fresh malarial cases had been sleeping—only one infection in about sixty dissections. In expectation of better success later, nothing was generally used in the earlier dissections except decinormal salt solution, and consequently some beautiful stomach infections spoiled before either drawings or photographs were made.

I felt discouraged at the small number of positive results, and went back to further study of the literature to find the cause. It was about this time that the first report of the commission from the Liverpool School to Sierra Leone came to my hands, and I was consoled to learn that the British workers had had precisely the same trouble. They offer several explanations. One is that certain Anopheles enjoy a natural immunity. Another and, I think, more correct reason, is that the conditions of the experimental bite are too artificial. To the mooted question I would add that in the tertian cases around New York, the sexual forms of the parasite (the "gametes") are undoubtedly rare, even in chronic and relapsing cases in which they are commonly said to be abundant, and that the use of quinine by the laity is so common that many of the parasites are already moribund before the patient comes to the experimenter's hands. I also hazard the conjecture that the gametes may be more numerous in the peripheral blood by night than by day. I have not, unfortunately, had the leisure at night to make any of the laborious studies that would be necessary to prove this.

[1] Philadelphia Med. Journal, May 5, 1900.

No one can realize without experience how much labor, time, and patience have to be expended to get any satisfactory results. It was not thought just to the patients to withhold quinine longer than was needed to examine the blood and establish the type of the fever curve. At this critical time the mosquitos, even when absolutely starved for six to eight days beforehand, would often refuse to bite. From twenty mosquitos starved for from four to eight days, I have frequently been unable to get more than two or three feeble bites. Sometimes they puncture the skin deeply in several spots and then pull away without sucking a particle of blood. Once a mosquito drew up just a "cropful" of blood (as I found on dissection a few hours later) and no more. Out of fifty or seventy-five bites I noticed but two cases in which just after the bite bloody serum was voided instead of water, though this was frequently noted by the workers in West Africa. No mosquito that had a "chipped" wing or a lame or absent leg would ever suck blood, though they would live indefinitely in tubes on sugar water.

I observed no "black spores" whatever in any of my successful dissections. There is a tendency now to believe that these bodies, as first described by Ross, may be explained in some other way, *e.g.*, as degeneration forms.

Whether a *single* infected mosquito can infect a man by biting is an interesting point which I tried to investigate with Dr. Cyrus W. Field, interne at the Presbyterian Hospital, who voluntarily offered himself. He was taken ill fourteen to sixteen days after his first bite with a chill and diarrhœa, from which he got well without quinine. No parasites were found in his blood on two examinations.

This point should be investigated further, for it has important practical bearings. Grassi's impression[1] seems to be affirmative. Bignami and Bastianelli[2] state that a single mosquito is even capable of inoculating several people, and these perhaps with more than one type of parasite. The writers do not, however, explain whether this is a normal or an exceptional occurrence.

Precisely how long an infected Anopheles remains dangerous is another interesting point, on which I have at present no definite data. I have already mentioned the doubtfulness of the survival through the winter of parasites in infected insects.

There are perhaps some exact notes already published on both these points in the Italian literature, much of which is unfortunately very inaccessible.

Of an immense number of malarial cases seen and examined during the summer, I found only one (a boy of seventeen, living on Tenth Street) who had apparently acquired his disease on Manhattan Island. Every one of the others had caught it elsewhere, or from the history could be supposed to have done so. I have not so far found a single Anopheles in Manhattan Borough, though of course no pretence is made that the search was thorough.

What other mosquitos will be found inculpated is a highly important field for American workers.

Anopheles crucians, of course, already bears a heavy *onus*. Other native species of Anopheles than the present three may be discovered when entomologists and physicians have given the matter further attention. Dr. Howard's remarks at the American Medical Association at Atlantic City last spring, urging that Psorophora and Megarhinus should be looked after, are just as timely now as then. Megarhinus is a southern genus; I have not so far been able to find Psorophora in the vicinity of New York. The genus Aedes appears to be rare, but it should not be dismissed

[1] Il Policlinico. Supplem., Anno vi., p. 1508.
[2] Tenth Cong. Soc. Ital. di Med. Intern.

without investigation. Nor should we feel absolutely sure that none of our native species of Culex can exceptionally carry the infection till at least C. pungens, C. tæniorhyncus, and C. triseriatus have been further examined. With C. pungens I have made a dozen or more inoculations, always with negative result.

Third. As to the period of incubation between the bite and the chill I have one valuable case to report.

Mrs. H. S——, East Seventieth Street, housewife, an intelligent and entirely credible patient. She had not been out of the city for several years before. She went to Fordham on the last Friday in August, to care for her sister, who was ill with malaria. She spent one night there and returned home next day. She was badly bitten by mosquitos. On the afternoon of the second Friday following (precisely fourteen days) she came down with a hard chill, which recurred Sunday and Tuesday and Thursday following. On this last day, when she finally sought medical advice, her blood was swarming with typical tertian parasites. A visit to the Fordham address given disclosed the interesting fact that the sister mentioned and her entire family (several children) had had chills and fever, and all but one had improved or recovered on Warburg's tincture. I inquired along the same block and found that there had been a veritable epidemic of malaria on that street for several squares. The mosquitos found were C. pungens in great abundance and A. quadrimaculatus in smaller numbers, all gorged with blood. The block was close to fresh excavations made for a sewer, and in the sunken centres of several vacant squares in the vicinity duck-pools of dirty water were seen.

Coldclough (W. F.)[1] reports from Oporto, Portugal, a case in which the exact period of incubation (from bite to chill) was definitely found to be eighteen days. The type of organism was unfortunately not determined. These cases are merely mentioned incidentally. The literature of the subject is extensive.

Fourth. Prophylaxis and eradication. Coming finally to this most important topic of all, a brief review of the literature alone would consume an entire evening. Important observations from original workers in all parts of the tropics are appearing daily, and the problem, for the tropical disease, seems to be gaining rather than losing in complexity. Some reports speak hopefully of the extermination of Anopheles; other observers (Koch,[2] for example) claim that Anopheles cannot be destroyed totally, and that the only hope for relief lies in rigid quarantine of infected human beings from the approach of the dangerous mosquitos, and systematic curative and prophylactic use of quinine, searching particularly for chronic and obscure cases and those among native children.

I wish to remark only upon our own local problem, which can be viewed with much more cheerfulness than the tropical one.

As a fair example of what may be locally accomplished I cite a small outbreak of malaria in a suburban New York town last summer. In August I was requested by one of the resident physicians to go there, examine the ground, and advise means of prevention. The conditions were briefly these:

Around a large pond in the vicinity of the town four or five fresh cases of malaria had recently developed. The first case was that of a coachman who had caught malaria elsewhere and had relapsed. From his quarters in a long row of stables at one side of the pond the infection had passed along to other stablemen and servants on the same side to the distance of a quarter of a mile from the original site. A quarter of a mile in another direction across the pond one other case appeared in a small child. A. quadrimaculatus was fairly abundant in every bedroom in that area in which a proper search was made. The breeding-places seemed to be segregated pools at the edge of the pond (the pond itself contained fish), and post-holes and excavations. These last were numerous, as many buildings were going up.

The following practical measures were recommended: (1) Extermination as far as possible, by a party of men sent out for the purpose, of all Anopheles found in houses and systematic introduction of screens in windows and doors. (2) Filling in of the smaller breeding-places, and drainage of the pond. (3) Continuous seclusion of every malarial patient by netting or otherwise from the bite of mosquitos while he had germs in the capillary blood; if possible, the sending away of the cachectic cases till danger of relapse was certainly passed.

These measures were intelligently put into operation at once; and the results were as prompt as they were gratifying. Not a single new local case of malaria developed. Anopheles disappeared promptly from houses where it had been previously a night terror, and Culex was greatly diminished in numbers. The local authorities expect during the coming spring to carry out the same measures even more rigidly, and believe that both mosquitos and malaria will entirely disappear there.

Inside the Greater City of New York the Health Department should take the following official steps:

(1) Require malarial cases to be reported, as scarlet fever and diphtheria are now. Malaria is at least as dangerous as scarlet fever; economically, it is far more of a scourge, for it affects adult bread-winners as well as children.

(2) Send an inspector to every infected house, who shall instruct the people to kill all the Anopheles in the house, to provide the windows and doors with screens, to isolate the patient with particular care from mosquitos, and to cause all the standing water in the vicinity to be drained or heavily petrolized. Rigid treatment with quinine should be insisted on, and the drug furnished gratis to those unable to pay, as diphtheria antitoxin is now supplied.

I believe that in a summer or two it would be possible by these measures to reduce the number of local cases by more than ninety per cent. If our Health Department could be induced to take these steps, even tentatively, and enforce them for two years, much useful attention would be attracted to the work, and the results, if even only half so encouraging as I have claimed, would intimately touch the health and material prosperity of every part of the temperate zone.

Of immense interest and value in this connection is the work of the Italians, Fermi and Tonsini, on the Island of Asinara.[1] This island is north of Sardinia, and is inhabited only by convicts. After a close study of the malarious localities measures were taken for (1) destruction of mosquito larvæ (petrolizing pools and emptying tanks and tubs completely twice a month); (2) destruction of adult mosquitos in the convict dormitories with pyrethrum powder, "zanzolina,"[2] chlorine gas, etc. (3) Protection of habitations against mosquitos by netting in doors and windows. Results in one season: Anopheles almost

[1] Lancet, October 20, 1900.

[2] See the masterly and largely convincing series of reports forwarded last year from the German and Dutch East Indies and published *seriatim* in the Deutsche med. Woch., 1900.

[1] Lancet, October 20, 1900, translated from Annali d'Igiene Sperimentale, 1900.

[2] "Zanzolina" is made of chrysanthemum powder, valerian root, and "larvicide." The last is an aniline dye. The smoke from the burnt powder paralyzes mosquitos in an hour (about a tablespoonful to a room of thirteen cubic yards) and eventually kills them. Doors and windows must be shut. The smoke is not disagreeable or injurious to the human air passages. Clavenzani, Il Policlinico, Supplemento, anno vi., p. 761.

never found (and Culex much more rarely than formerly) in dormitories. Not a single local case of malaria, the new cases, nine in number, being all importations or relapses. The previous year there were ninety-nine cases, forty-four originating in the island.

Still more instructive and convincing are the recent accounts from Grassi and Celli[1] of the efforts made to protect the railway employees of Italian railways passing through the dreadfully malarious regions of Lazio (Latium) and Salerno in southern Italy. Briefly, the precautions taken were these:

Employees were required to stay indoors from sunset to an hour after sunrise. The doors, chimneys, and windows of dwelling-houses and stations were fitted with wire screens, and a kind of "storm-door" or vestibule (also of wire gauze) was placed before each entrance. Night workers were provided with masks for the face and thick gloves (of cotton or chamois) for the exposed parts of the forearms and hands. The inside walls of the houses were painted white in order that any Anopheles that might accidentally enter could be seen and killed. This was all. But the results during the past summer have been miraculous. While houses and villages around sickened to a man with the gravest types of malaria, practically not a single case of fresh malaria appeared in the protected stations. Experiments by Celli (*l.c.*) even on the straw huts of the lowest class of the peasantry were nothing short of marvellously successful.

As to more general prophylactic measures, public education is urgent. The present obstinately erroneous views of the origin of "mosquito fever" should be more earnestly contested by the physician. The little pamphlet on "Prevention of Malaria," issued early last year from the Liverpool School of Tropical Diseases, could be made very useful. It has been reprinted or reviewed extensively in America. The doctor should be able to tell Culex and Anopheles apart, and warn his patients not to pass the matter off —as they now universally do—with a jest. As Dr. Patrick Manson (to whom the world owes a great debt in the work attending the discovery of the etiology of malaria) has so earnestly urged,[2] protection from the bite of mosquitos at night in the bedroom is the greatest essential. As long as this is thoroughly accomplished, the existence of Anopheles, infected or uninfected, in a given region (at least in the temperate zones) is not much more significant than the presence of Culex. I say "not much more" advisedly, for daytime infections can occur. They are, however, rare.

Speaking for our own environment, the more I have considered the suburban conditions and the character of our soil and drainage, the more dubious I feel whether Anopheles can be more than reduced in numbers for years to come.

Public works and private buildings in our suburbs are constantly going forward. The coincident upturning of undrained earth and the formation of rain-pools are ceaseless. The present plan of raising miles and miles of streets above grade, and leaving the owners to fill in the squares at their leisure has created thousands of sunken squares in Bronx, Queens, and Brooklyn, where great ponds of stagnant water stand for half the year. Over these a green scum is forming by the middle of June, and if Anopheles does not find these pools, nothing but Providence has prevented it. A rain pool in midsummer anywhere, lasting about two weeks, is all one insect needs to make one thousand. Anopheles, like Culex, can breed with equal readiness in sluggishly flowing streams where fish are absent, and not even an advanced degree of putrescence or contamination seems to kill them.

[1] Il Policlinico, Supp., *l.c.*
[2] Lancet, September 29, 1900.

At the same time, for the reasons already stated, I believe that our local malaria can speedily be eradicated by attacking the problem from other directions. We shall need (1) systematic governmental measures along the lines I have suggested; and (2) ready ability on the part of medical advisers generally to make the microscopic diagnosis in irregular and obscure cases.

For much courtesy and kind assistance I wish to make acknowledgments to the following gentlemen, besides those already named: Dr. Robert J. Carlisle; the House Staff and Visiting Physicians of the Presbyterian and Bellevue Hospitals; the House Physician of Fordham Hospital; Dr. Charles F. Roberts, of the Board of Health; Dr. L. O. Howard, of Washington, D. C.; Dr. E. C. Rushmore, of Tuxedo; and the Editor of the MEDICAL RECORD.

121 EAST TWENTY-SIXTH STREET.

THE CAUSATION, PREVENTION, AND TREATMENT OF GOUT.[1]

BY ALEXANDER HAIG, M.A. AND M.D. OXON., F.R.C.P. LOND.,

AUTHOR OF "URIC ACID AS A FACTOR IN THE CAUSATION OF DISEASE."

GOUT is not a constitutional disease due to any defect in the formation or functioning of the body. It is a form of diet disease due to food poisoning. It follows from this that it can be cured by leaving off the poisonous foods, and prevented by omitting such foods from the diet of the young. Gout is rheumatism, and rheumatism is gout. The arthritis of both is due to the irritation produced by uric acid.

Causation.—When the possibility of introducing uric acid into the body and blood by swallowing it like other poisons was neither understood nor believed in, it was naturally concluded that gout was not due to poisoning but was a constitutional defect or disease.

I believe I was the first to point out in a paper in the *Journal of Physiology*, vol. xv., published in 1893, that the experiments on which these erroneous beliefs were founded had serious flaws in them, flaws which were due to the generally prevailing ignorance of many of the conditions that control the solubility of uric acid in the blood, and its excretion in the urine. But once these conditions had been followed a little more closely and in experiments extending over considerable periods of time, it soon became evident that one had only to administer a few grains of uric acid while taking care to keep the blood in a condition to dissolve them and hold them in solution, to find them appearing with the greatest punctuality in the urine grain for grain as administered.

As will appear later on, we can do much more than this now, and can actually watch the passage of this administered uric acid through the blood, by noting its effects on the circulation.

This knowledge at once raised two questions: (1) How much uric acid is introduced into the body in the food of any ordinary day? (2) Will the uric acid thus introduced suffice to account for all the uric acid of disease?

The answer to the first question is, I think, that from five to seven grains a day of uric acid may be easily introduced in ordinary diet in such things as tea, coffee, soup, meat extracts, fish, and meat.

The answer to the second question is that these quantities if all retained in the body will mount up and form four to six ounces of uric acid in the year, and though under ordinary circumstances nothing like the whole of this amount is retained in the body, such

[1] Read before the Cambridge Medical Society at their November meeting, 1900.

an extensive introduction going on year after year for thirty or forty years with even quite a small retention, will easily furnish all the uric acid that we ever see inside a human body.

One other fact we have to bear carefully in mind is that introduced uric acid interferes with the solubility and so with the excretion of the uric acid that is formed in the body. For every one forms uric acid every day in about the relation of thirty-five grains of urea and one grain of uric acid for each ten pounds of body weight, and the man who suffers from gout probably forms no more uric acid in relation to urea than any one else does.

On the other hand, if the reverse were true, if the gouty man from some defect in structure or function formed more uric acid, either relatively or absolutely, than any one else, this would go on in spite of diet and drug treatment, and it would be impossible either to prevent or cure gout or other uric-acid diseases.

As a result of this effect of introduced uric acid on the solubility of uric acid in the blood, a man who forms ten grains of uric acid a day, and introduces other four or five grains each day in his food, will probably fail to excrete all the uric acid he has to deal with, and will soon accumulate a more or less large store in his body. On the other hand, the man who forms ten grains a day, but introduces only one grain a day, may very probably excrete day by day all the uric acid he has to deal with, and may consequently never form a store or accumulation at all. In other words, all the uric acid of formation does no harm provided that a large amount of introduction is not added on to it.

I must guard against misunderstanding by saying that the above is true only when no more than the physiological allowance of albumen is taken (*i.e.*, that which suffices to produce from three to three and one-half grains of urea per pound of body weight per day). But if this quantity be exceeded, there will, of course, be an increased formation both of urea and uric acid, but still in the relations of one to thirty-five; and as a large nitrogenous metabolism means for obvious reasons a diminished alkalinity of the blood, some of the formed uric acid may be retained and produce an accumulation.

It is necessary, therefore, to look to two points: (1) To introduce into the body as little uric acid as possible. (2) Not to take more than a physiological allowance of albumen.

Probably a considerable number of those who are gouty to-day have for years been breaking both these rules, and their sufferings are the result of their doing so. Still of the two, introduction is by far the larger and more important factor, so that we are justified in saying that gout in this country is due to poisoning by animal flesh and tea.

Speaking generally, the muscles of animals may be said to contain uric acid to the extent of from two to seven grains to the pound, and their viscera (liver, kidneys, etc.) from five to twelve grains to the pound, and these quantities are introduced into the bodies of those who swallow them.

Then the alkaloids of tea, coffee, and cacao are, as is well known, xanthins, and these are for physiological and pathological purposes equivalent to uric acid; and several other vegetable substances, as peas, beans, and lentils, contain considerable quantities of xanthins, some of them even twice as much as meat. And as regards the xanthins I have shown that their administration produces just the same effects as the administration of uric acid.

We have thus seen where the uric acid comes from; we have now to see how it acts, and for this purpose we may divide its effects into two classes: (1) The local irritation it produces in the joints and fibrous tissues (gout). (2) The general symptoms, often called gout in the blood, the circulation conditions, high blood pressure, etc.

The first has always seemed to be fairly simple, for uric acid is an irritant of tissues, especially when it is in solution; thus Ebstein showed years ago that uric acid in solution with phosphate of sodium produced irritation of the cornea when injected into it, while the phosphate solution alone produced no irritation.

Then Pfeiffer, of Wiesbaden, made some interesting experiments by injecting urates in suspension under the skin; and then he found that when alkalies were taken the urates caused local irritation; but if acids were taken the irritation diminished. In other words, the urates in suspension caused little irritation, but when they were got into solution with the alkali the irritation was increased.

And this is exactly what we see in our daily work, for drugs, like iodides, sulphur, and lithia, which diminish the excretion of uric acid in the urine, nevertheless relieve the pains of chronic arthritis.

Under some conditions also the use of alkalies may make the pains of arthritis worse: that is, when the alkali merely suffices to increase the solubility of the urate but not to remove it from the focus of irritation. The more powerful solvents, the salicylates, relieve not because they get the urates into solution, but because they remove them from the irritated joints and from the body. (See "Uric Acid," ed. v., Fig. 62.)

On the other hand, we see the biurate of sodium lying deposited in various parts of the human body without the smallest sign of irritation or inflammation round it. Hence we see that urates in solution are irritating, but urates deposited are not.

Another fact which points the same way is that the biurate of sodium takes two to three days to be thrown down from its solution in serum, while wine will often produce an attack of gout in as many hours, even before the patient leaves the dinner table; obviously, then, this attack of pain cannot be due to the throwing down of the biurate which has not had time to take place, but it must be due to a concentration of uric acid in the part, either in solution or in colloid form.

The biurate is a subsequent result of the gout attack, and with the throwing out of the biurate the irritation and inflammation subside, and we find it weeks, months, or years afterward lying perfectly quiet in the tissues, its owner having possibly forgotten all about the attack of gout he once had.

In the blood at the time of the gout attack we have to deal with uric acid or urate containing more or less alkali, and either in solution or colloid form like that which is thrown out from solution in phosphate of sodium on cooling or treating with a dilute acid. And it is the concentration of this urate in either strong solution or colloid form in certain fibrous tissues that produces the local irritation and pain. And the reason it so generally selects the fibrous tissues is that these being less vascular than many other tissues and less well supplied with alkaline blood, have greater difficulty in keeping up their alkalinity, and when this is diminished by any local cause, as cold and wet, or by a general cause, as the taking of acid wines or beer, the urate of the blood is rendered less soluble in these tissues and is retained there probably in colloid form, producing more or less local irritation according to the amount present in the tissues, and the time during which it is able to act.

Then the rule about the action of drugs is this: that all substances that increase the power of the blood to hold uric acid in solution tend to remove it in solution from the joints and fibrous tissues, and to diminish the irritation in them; while, conversely, all substances that diminish the power of the blood to hold uric acid in solution tend to cause its retention and accumula-

tion in the joints and fibrous tissues, and to increase the irritation in them. And when we come to deal with the blood and circulation, we shall see that all substances that increase solubility increase the amount of uric acid in the blood, while all substances that diminish solubility diminish the amount in the blood. We shall also see that the quantity in the urine always corresponds with the quantity in the blood, and that our power of control is so great that we can make the quantity in either fluid almost anything we like.

The chief substances that increase the solubility of uric acid in the blood are alkalies and salicylates, and heat has a similar effect, as it increases the passage of acids out of the body in perspiration, thus acting like a dose of alkali and increasing the alkalinity of the blood; these tend to prevent the irritation of fibrous tissues by uric acid, or to diminish such irritation when present by removing and excreting the uric acid.

The chief substances that diminish the solubility of uric acid in the blood are the acids and many metals that form insoluble compounds with uric acid, and cold naturally has the reverse effect to that of heat, preventing the excretion of acids in perspiration and diminishing the alkalinity of the blood.

Hence, the arthritis of gout or rheumatism (for both are due to uric acid) may result from exposure to cold, or cold and wet, the taking of acid wines or beer, or contact either internally or externally with many of the common metals, such as mercury, lead, zinc, and copper, etc.

Second. The general symptoms of gout depend chiefly on the fact that uric acid controls the capillary circulation of the whole body. It is probable that being in solution with phosphates in the blood, it is under certain circumstances thrown out in the circulation as bulky colloid masses, more or less similar to those obtained when a solution of uric acid in phosphates is either cooled quickly or treated with dilute acids; and the control of the capillary circulation is probably due to the capillaries being obstructed by the colloid granules. (For fuller treatment of these points I must refer to my work on "Uric Acid.") But be this as it may, the fact remains that a careful measurement of the rate of the capillary circulation by the methods that I shall show presently is an absolute guide to the amount of uric acid in the blood; for the capillary circulation not only varies from morning to evening in accordance with the physiological variations in the excretion of uric acid, and the amounts in the blood and urine, but it can be made to vary at any time and in any direction at pleasure by altering the quantity of uric acid in these fluids—which it is quite easy to do.

Perhaps a few definite figures will make this more easy to understand, and we have now also an absolute guide to the amount of uric acid in the blood in the number of granules precipitated in a drop of that fluid drawn from the end of the finger by the addition to it of a drop of a twenty-per-cent. solution of ammonium chloride. These granules bear a relation to the red cells in physiology of say 1:8 in the morning, 1:18 or 1:20 in the evening, there being much more uric acid in the blood and urine in the morning, as is well known. In pathology they may be anything from 1:1 in Bright's disease to 1:40 in fevers, and by the action of salicylates they may be made 1:5, 1:2, or even 1:1 in the first few hours on the drug, and they fall to 1:50 or 1:70 the day after it has been left off, corresponding exactly with the fluctuations in the excretion of uric acid in the urine. Then in physiology it is possible, by feeding uric acid, to make the day's excretion in the urine vary from twelve grains up to thirty grains, and the granules in the blood alter in the corresponding ratio.

Lastly, we must remember that obstructed capillaries in front, with a strong heart behind, means of necessity high blood pressure in the vessels between them, and this is the explanation of the uric-acid headache, to which I used to be a martyr, and in this disease the high blood pressure causes undue pressure within the skull, and pain is the result.

I have called the return of the blood into capillaries blanched by pressure the "capillary reflux," and a careful measurement of the time this takes is the measure of the quantity of uric acid in the blood, and all the other phenomena, the number of granules in the blood and the blood pressure, vary with this.

Thus, the capillary reflux measured by a metronome beating half-seconds is in the morning six or more half seconds, in the evening three or four half-seconds, and we get the following grouping of events:

	Capillary reflux—half-sec.	Blood pressure—mm. Hg.	Granules in blood.	Uric acid relation to urea in urine.
Physiology, morning.....	6	120	1: 8	1 18
Physiology, evening	4	100	1:18	1:30
Fevers.....	2–3	70–80	1:40	1:50
Bright's disease.....	10–14	170–180	1: 2	1:15

There is one other easily observed result which agrees with those just mentioned in every way, and that is the urinary water; for obstructed capillaries in the skin and slow capillary reflux are the index of similarly obstructed capillaries throughout the body, and obstructed capillaries in the kidney mean that the water of the blood has difficulty in passing through the kidney into the urine; hence it follows that the urinary water under all conditions varies in the reverse direction to the uric acid excreted along with it: if the uric acid is rising the water is falling, and vice versa, for excess of uric acid in the urine means, as we have seen, excess in the blood, and excess in the blood means obstructed capillaries throughout the body, and obstructed capillaries in the kidney mean scanty excretion of water from the blood.

Hence, the urinary water is not only scanty in the morning and profuse in the evening, the reverse of the uric acid, but it follows every fluctuation in the excretion of this substance throughout life, whether due to physiology, drug action, or pathology, and by controlling the uric acid we can also make the urinary water anything we please. It thus furnishes us with a ready index of what the uric acid is doing and with one more easily observable proof of the enormous power which this substance has in controlling the circulation, and so the physiology and pathology of the body throughout life. And, as I have said already, by means of drugs or feeding uric acid, we can produce results similar to almost any of the above at pleasure.

Lastly, these changes in the quantity of uric acid in the blood and the alterations in the rate and completeness of the capillary circulation, affect the quality of the blood itself, and thus uric acid is the cause of all the common forms of anæmia. Thus, the blood decimal, which is obtained by dividing the percentage of hæmoglobin by the percentage of cells, is not only found to vary up and down from morning to evening with the above factors, but by means of drugs on the one hand, or feeding uric acid on the other, it also can be made almost anything we like, as with the capillary reflux, the blood pressure, the granules, and urinary water mentioned above. And this has led me to produce a card for the approximate estimation of the blood decimal from the color of the tongue, gums, etc., because of the valuable information we thus obtain as to the quantity of uric acid that is or has been passing through the blood. Thus, while the capillary reflux will tell us the quantity of uric acid in the blood at any given moment, and enable us at once to

distinguish between Bright's disease on the one hand and fever on the other, the blood decimal will tell us whether much uric acid has been passing through the blood in hours, days, or weeks, according to the intervals at which we examine it, and I commonly make use of the card to tell me from the color records it gives whether patients I see only after intervals of weeks or months are doing well or otherwise, *i.e.*, whether their blood decimal is going up steadily, the general result of stopping the introduction of uric acid, or whether it is stationary or descending, owing to their having perhaps a very large store of uric acid in their bodies which is constantly passing through the blood.

We have seen, then, as regards causation:

(1) That gout is due to poisoning by flesh and tea and similar substances, which introduce uric acid into the body in very considerable quantities.

(2) That the uric acid so introduced may not only remain in the body, but may prevent the excretion of the uric acid formed in the body.

(3) That as a result the body becomes more or less saturated with uric acid, which may irritate its fibrous tissues (gout or rheumatism) or may obstruct its capillaries, causing high blood pressure and defective capillary circulation and their results, such as the great group of circulation diseases, the uric-acid headache, epilepsy and mental disease, anæmia, Bright's disease, Raynaud's disease, etc., all of them being mere results of the enormous influence which uric acid exerts on the circulation of the body by obstructing its capillaries.

(4) That all these diseases, which have been called by so many names, fall into two groups: (*a*) the local group, and (*b*) the circulation group; of which the latter is by far the more extensive and important, so that what we used to call gout and rheumatism become almost insignificant by comparison.

In the future they will all, I hope, be called uric-acid poisoning, and be recognized as due to unnatural food.

The proof of this lies in our new possibilities of prevention and cure; for real knowledge of the real truth always means power, and when there is no power there is no real knowledge.

Prevention follows so simply from the above considerations that it need not detain us; it consists in removing from the diet of the young all substances which contain a notable quantity of uric acid. This is, I believe, not only invariably successful in warding off the above forms of poisoning, but it conduces through its circulation effects to a glorious development of both mind and body, to which in the past we have been strangers. And when the change has been made future generations will look back on our records of sorrow, suffering, and degradation with amazement.

Treatment.—This, again, follows simply from causation, and we have only two things to do: (1) To cut off the poisons that have been the cause of the trouble, so that introduction shall as far as possible cease. (2) To provide for the elimination of the poison already in the body.

Diet meets the first indication, and for its alterations and the methods of carrying them out I must refer to my book on "Diet and Food." It is merely necessary to see that a proper quantity of albumens is taken in relation to the weight, and that these albumens are got from substances that contain little or no poison.

One result of thus altering the diet will be that the body will gradually clear itself of the accumulated uric acid it contains, for uric acid introduced interferes, as we have seen, with the elimination and excretion of uric acid formed or contained in the body.

It follows that all diseases due to excess of uric acid in the tissues or blood will slowly get better as the result of altering diet alone. And this we find to be the case, joints slowly get less stiff and painful, recurrent attacks of irritation gradually get less painful and prolonged, till at the end of eighteen to twenty-four months such manifestations often cease. On the side of the circulation similar slow changes ensue, the capillary reflux gradually quickens, the blood pressure falls, the color improves, and the blood decimal rises in value: in some cases even in six months the capillary reflux and blood pressure may have moved more than half-way to normal, and by the end of twelve to eighteen months the blood decimal ought to have gone up at least twenty per cent.: I say ought, for this depends in part on nutrition, and if the albumens are deficient the decimal may remain stationary or rise but little; hence, by my color card I can gauge not only the quantity of uric acid, but the sufficiency of the food. It is, therefore, only in a few special cases that we need to use drugs at all, for in the majority Nature will put things right if you free her from the poisons by ceasing to swallow them. Acute arthritis is one of these conditions, and the drug (a salicylate) that is used in the acute arthritis called rheumatism is, in my opinion, the best drug for all these forms of arthritis. The only points that require attention are to give the salicylates alone (or, if with other drugs, not on any account with alkalies, which interfere with their action), and also to give enough of them. And one of the best proofs that the arthritis of acute rheumatism is due to uric acid is the fact that while the arthritis is at once subdued by a salicylate in proper doses and alone, it may not be subdued at all, but may be even made worse if the salicylates are given with alkalies, or if the patients are kept hot and allowed to perspire, conditions which increase the alkalinity of the blood. Hence, also, salicylates are of but little use in the acute arthritis of hot climates, or in this country in very hot weather, unless special precautions are taken to keep the patient cool.

If rheumatic fever was due to a microbe, as some suppose, and if the salicylates acted as antiseptics merely, then they should produce as good effects in hot climates as in cold, and with alkalies as without. Clinical experience, however, does not show this to be the case, and the explanation as regards uric acid is simple enough, for salicylates with alkalies, or in conditions of heat and perspiration, are not solvents of uric acid, and do not increase its excretion in the urine; but given with acids or in cold weather, which diminishes the alkalinity of the blood, they are good solvents of uric acid and greatly increase its excretion in the urine. My old law, formulated some years ago, was, "all substances which increase the solubility of uric acid in the blood do good in the arthritis which is due to it"; but under some conditions salicylates are not solvents, and therefore do harm—not good. Alkalies are solvents by themselves, and salicylates by themselves; but the two together are not solvents, do not increase the solubility and excretion of uric acid, and therefore do harm instead of good. Every one knows that salicylates act much better and with greater certainty in acute arthritis with high temperature than in chronic arthritis with normal or subnormal temperature; and the explanation is again simple, for fever means quickened metabolism with its result, increased acidity of the urine, and diminished alkalinity of the blood, conditions which favor the solvent action of salicylates.

In subacute and chronic conditions we have to do all we can to diminish the alkalinity of the blood, which is high, in order to favor the best action of salicylates. Exactly the same holds for the acute arthritis of gout: give salicylates alone and plenty of

them, and on no account with alkali or colchicum, as these increase the alkalinity of the blood.

Again, do not when giving salicylates cut off wine and cut down meat; my gouty patients are told to keep on with both as usual, for both tend to keep up the acidity of the urine and diminish the alkalinity of the blood, which is what we want with salicylates. The time to alter to a uric-acid-free diet is later on when the salicylates have cleared out most of the uric acid and can be left off, as the arthritis has gone. If for the same reason I am called to see a case of gout that has already had colchicum, I feel that I see it too late to give salicylates; the field has been spoilt for them. Possibly by giving acids and wine, and, perhaps, some opium with the salicylates to counteract the evil effects of the colchicum, they may still succeed; but this cannot be counted on with certainty. If the colchicum has obviously produced much depression, and if for any reason the wine, opium, etc., cannot be given, it is better, in my experience, to continue the colchicum and alkalies, and not to attempt to give salicylates at all. These latter are far the best drugs if the conditions favor their action, but there are other conditions (debility, heat, perspiration) in which they can only do harm and make the arthritis worse.

What has to be always remembered is that acute conditions with fever and high acidity of urine favor the best action of salicylates; while conditions of debility with normal or subnormal temperature, perspiration, and all that favors perspiration (as hot climates) with slightly acid or alkaline urine, are most unfavorable to their action as solvents. And this holds for all diseases that are due to uric acid and not merely for arthritis; and, in all, the reaction of the urine may be taken as a useful guide as to whether it is right to administer or to withhold these substances.

My own rule in chronic arthritis is to give wine and a generous diet (by no means strictly free from uric acid) and some salicylic acid, which has (as we should expect) more power than any of its salts to overcome the low-acidity conditions of subnormal temperature and debility. Some opium may be given with the salicylic acid to aid its action, and this is specially indicated if there is increased action of the bowels, which should be restrained. One need not expect very prompt action in chronic conditions, but still within two or three weeks there should be some improvement.

The only other conditions of which I need mention the special treatment, besides the arthritis we have been considering, is the high blood pressure of chronic gout due to a large excess of uric acid in the blood. As this may be a danger to the vascular system itself, to the brain and other important nervous structures, or may seriously injure the nutrition of the skin, liver, or kidneys, it may require prompt treatment by drugs, which will hold it in check till the diet has had time to act. Many drugs are available for this purpose, all those, in fact, that in one way or other diminish the solubility of uric acid in the blood, and clear it out of that fluid. And it matters not how you clear it, for as the uric acid in the blood and urine diminish, the capillary reflux will quicken, the blood pressure will fall, the blood decimal will rise, the urine will increase, and it will be quite evident that the fall of blood pressure is not due to debility or a weak heart, as the patient will be stronger and able to do more than in the condition of high blood pressure, and will feel buoyant and cheerful.

The drugs I have most commonly used to clear the blood of uric acid are the iodides, as iodide of sodium, more or less aided by the chloride and bromide of ammonium and chloride of sodium, which I sometimes call sea-water mixture; a little mercury given with iron to prevent salivation may be also taken along with them, as in the treatment of Bright's disease, described in "Uric Acid"; in fact, these dangerous high-blood-pressure conditions are practically equivalent to Bright's disease, whether there is albumin in the urine or not. Several other things act in exactly the same way as other metals (copper, zinc, silver, gold) or lithia, and may succeed best in special cases; but I have more often used the things first mentioned.

I shall not go further into the drug treatment of the circulation diseases of uric acid here. I will only say in conclusion that in using any of these drugs or metals to clear the blood of uric acid you may often illustrate for yourselves the pathology of arthritis by producing an attack—the uric acid which you drive out of the blood may go into the fibrous tissues or joints and the whole series of changes above described in the blood and its circulation and in the urine may be easily observed as they pass before you. The patient will say he has had a relapse of his gout, and you will know why he has had it.

THE NON-MYXOMATOUS CHARACTER OF NASAL POLYPI.[1]

By JONATHAN WRIGHT, M.D.,

BROOKLYN, N. Y.

Mr. Chairman and Gentlemen: In accepting your invitation to present a short paper before this meeting, I have done so with the hope of saying more forcibly and emphatically some things which I have, until lately, supposed were too well known and too universally accepted by rhinologists for explicit reiteration. I refer to the necessity of regarding nasal polypi[2] as pendent tissue in the nose, which has assumed that shape because of the effusion of serum into it from the blood-vessels. I had supposed that no one now used the word myxomatous in connection with these growths except in a Pickwickian sense.

It is of small consequence what name is attached to any phenomenon of nature, so long as it does not lead to confusion of thought. We all use the word adenoid, and we all know exactly what is meant by it, although the etymology of the word is very far from clearly indicating the histological structure or the anatomical locality of its occurrence. With the mistaken use of the word myxoma, however, there appears still to linger a mistaken conception of the condition to which it refers in the nose. Many very competent rhinologists, and even some familiar with histological work, conceive of this condition of the nasal mucosa as a new growth of tissue, a proliferation of embryonal branching cells in a homogeneous mucoid fluid of a different chemical and tinctorial reaction from ordinary serum with a little mucin in it. Now such is not the case. While in the fluid of a polyp there is some mucin derived from glandular structure the polyp may contain, while here and there by careful focussing an occasional embryonal new connective-tissue cell may be seen, there is little or no new formation of tissue, but on the contrary a separation of the fibres of the pre-existing subepithelial stroma by serous effusion. In not a few cases these stroma fibres are so scanty or the effusion of serum is so directly under the epithelium that the coagulated fibrin threads form the sole framework of the tumor holding a few leucocytes in

[1] Read before the Southern Section of the American Laryngological, Rhinological, and Otological Society, at Richmond, Va., December 1, 1900.

[2] It is hardly necessary to say that I here refer to the ordinary gelatinous polyp, and that I am aware that the word polyp is strictly only referable to external conformation and not to internal structure. What I have to say refers also as well to the so-called polypoid degeneration in the nose.

their meshes. I shall not go further than this into the histology of the subject. I have elsewhere done so exhaustively. As for the histology of the so-called true myxoma, that may be found in all the text-books on pathology. In not one of them will you find any drawing illustrative of their structure which has been made from an intranasal growth, though nasal polypi occur more frequently than all myxomata of all other localities put together—perhaps more frequently than all other benign tumors put together, Zuckerkandl asserting that they are to be found once in every eight or nine bodies on the post-mortem table. Surely if real myxoma occurs in the nose, one typical enough for text-book illustration ought to be found in a place where they are apparently so common rather than elsewhere, being in all places exceedingly rare, acording to Virchow.

In the few minutes which are allotted to me, I am going to review hastily the salient historical points in this matter, so that from another standpoint than the one from which I have hitherto spoken of the subject there will remain no doubt as to my assertion that a very pernicious error has crept into the common conception of these growths.

I need only mention that polypus is a term meaning many feet, used by Hippocrates ("De Morbis," ii.) to designate five kinds of morbid intranasal states, only one or two of which would now be called by that name. The first feeble attempts at pathological differentiation is to be noted in Galen, who speaks of nasal growths thus ("Definitiones," No. 370): "Sarcoma is the unnatural growth of flesh in the nostrils, and a polyp is a kind of sarcoma. A sarcoma differs from a polyp in size and structure." It is plain, therefore, that Galen's idea was that of a new growth of tissue. It is unnecessary to follow exhaustively the various interpretations of this Galenic pathology throughout ancient medical history. Suffice it to say that the Arabians described a form of polyp in the nose which they called a hemorrhoid, considering it analogous to the vascular tumors at the other end of the alimentary canal. We recognize in this, of course, our vascular hypertrophy. When the pre-Renaissance physicians translated the Arabian works into execrable mediæval Latin, polypus was frequently rendered scorpio, because, I presume, that was the kind of a many-footed animal with which they were most familiar.

It is not until the last years of the seventeenth century that much advance may be noted over the pathology of Galen. Dionis,[1] a French surgeon whose work was published in 1707, says—and the statement was probably not original with him—it is proper to make a distinction between the two kinds of polypi. One is an excrescence formed by the engorgement of the glands which line the walls of the pituitary membrane, and the other is the "extension of this membrane gradually elongated." About this time Boerhaave could account for the formation of polypus only by supposing that "the nasal passages and the nasal mucous membrane become clogged with mucus and cannot discharge the humors contained in it." To add a touch of humor to this arid narration, it may be noted that Juncker,[2] a fluent and distinguished medical writer, in 1721 insisted that, according as the moon fills or wanes, the nasal polyp increases or diminishes in size. Without discussing astrological influence, we may see that the conception of the polyp had thus early changed to that of a water-logged membrane. Gorter,[3] in 1742, embodies the idea more clearly thus: "It seems sufficiently evident that the pituitary membrane is separated from the bone, often carious, in the cavity of the nostrils, so that it makes a pendulous sac, either simple or multiple, according as this membrane is separated from one or more depressions of the small bones, which sacs swell with secretions collected in the cellular lamellæ of the membrane." It is unnecessary to quote from Morgagni,[1] who published his great work twenty years later, in order to show that his conception of the structure of the œdematous polypus of the nose was the same.

We may take a leap across a hundred years to the remarks of John Watson, surgeon to the New York Hospital, who in 1842 published a paper called "An Inquiry into the Pathology and Treatment of Polypous Tumors of the Nasal Fossæ":[2] "Soft polypi . . . arise from obstruction or obliteration of the ducts of the muciparous follicles and consequent retention and accumulation of the mucus within these; they lead to thickening, consolidation, or infiltration of the mucous membrane and subjacent cellular tissue; they acquire their pendulous position and pedunculated attachment by the yielding and growth of the tissues enveloping the mucous accumulation, and by the naturally loose attachment of the pituitary membrane here to the subjacent parts." He drew his ideas from Chelius' "Handbuch der Chirurgie,"[3] first published shortly before this, in which it is asserted that they arise as œdematous swellings of the separate folds of the mucous membrane hypertrophies together with the submucous tissue at certain localities.[4] Thus far, since the disappearance of the Galenic pathology, there has been nothing said in regard to the proliferation of tissue, and it is evident that the common-sense view of the pathogenesis of nasal polypi prevailed in this country as well as abroad in the earlier years of the past century.

On referring to an early (1854) American edition of Paget's "Surgical Pathology," we find he classes nasal polypi among the fibro-cellular tumors (p. 386), and in this class he also puts those growths shortly afterward described by Virchow under the name of myxoma. All modern pathological nomenclature and classification dates back to the "Morbid Tumors" of Virchow, who, after the vicissitudes of more than fifty years on the stormy German ocean of pathology, may still be felicitated on having the clearest head in Europe.[5] In the "Krankhafte Geschwülste" (ed. 1863, p. 417), having previously described myxoma in other publications, he dwells upon the relationship it bears to the retrograde metamorphosis of fatty tumors and of fat tissue, being frequently therefore found in connection with lipomata, a kind of tumor, so far as I know, never observed in the nose. He distinctly states that myxoma "in adults is relatively infrequent even in the atrophic metamorphosis of fat tissue in the mucous membranes." It is not the place here to enter into a discussion if Virchow was right in setting up this class of growth as separate heterogeneous tissue proliferation. It may be that myxoma is only a variety of connective-tissue proliferation infiltrated with serous exudate.[6] I am not able to speak as to that. What I desire to insist upon is that the ordinary nasal polyp

[3] P. 530, seventh edition, 1852.
[4] I have not been able to see the original of Frerichs' dissertation "de Polyporum Structura Penitore," 1843, but he is said to have first pointed out that the epithelium covering nasal polypi was the same as that of the surrounding mucosa (Heymann's "Handbuch").
[5] See his late address at the Medical Congress in Paris, Virchow's Archiv, Bd. 162, Hft. i.
[6] In his address referred to above, he remarks incidentally as to this matter: "Es ist ein blosses Spiel mit Worten, wenn man junge pathologische Zellen und Gewebe embryonale nennt." Some account of the question of the doubt as to Virchow's classification of myxoma may be readily found in Councilman's article on "Myxoma" in Wood's "Reference Handbook of the Medical Sciences."

is not essentially a proliferation of embryonal tissue or of any other kind of tissue, nor is it a metamorphosis of tissue. I need only refer in passing to the remarkable mistake made by Billroth,[1] in ascribing the structure usually found in rectal polypi to those found in the nasal cavity. He says he examined twenty cases of nasal polypi, and they were nearly all adenomatous in structure. This, of course, we know is wrong; they frequently contain no glandular structure at all, and never, in the ordinary polyp, are the glands more abundant than in the normal mucosa.

It needs only a reference to a few of the modern text-books on pathology to show that the definition of Virchow, in spite of much well-grounded criticism, is still universally accepted, and yet in not a few of them has crept the idea that the structure of the nasal polyp conforms to it. Billroth,[2] Cornil and Ranvier (1884) follow him explicitly. Birch-Hirschfeld (1887) speaks of nasal polypi as soft fibromata or myxofibromata (vol. ii., p. 381), but evidently he had no experience of his own with these growths, because in his description of myxoma (vol. i., p. 151) he describes them in the sense of the others. He misquotes Hopmann, who, as we shall see presently, directly repudiates the idea of myxoma of the nose. Weichselbaum (1892) gives a characteristic woodcut and the usual description of true myxoma. Ziegler (ed. 1895) says that nasal polypi are made up of œdematous connective tissue and mucous tissue, and must therefore be ranked among the fibromata and myxomata (vol. ii., p. 625), but he differs in no way from other pathologists in his description of the latter (vol. i., p. 397), which are always combined, he says, with the histological forms of other tumors. Delafield and Prudden, in the last edition of their "Pathological Anatomy," state that it is frequently difficult to distinguish between the two; but in the illustration they give of the structure of a mucous polyp of the nose, there is no resemblance to the picture they give under a higher amplification as typical of myxoma.

Evidently, therefore, while the pathologists are united enough as to the characteristics of myxoma, they have accepted the authority of others as to the occurrence of it in the nose.

When we attempt to find who was responsible for the introduction of the term into nasal pathology, we are baffled by the apparent insidiousness of the process. It seems to have crept in through its use by writers who were either unfamiliar with the myxoma of Virchow or else unfamiliar with the histological details and the pathogenesis of nasal polypi. Too frequently it has been indiscriminately used by writers unfamiliar with both.

The first mention of a myxoma occurring in the nose which I have been able to find is a report by S. W. Gross in 1871.[3] We find here the myxomatous error in full bloom.

A glance at the text-books on the nose, which began to appear first a quarter of a century ago, convinces one that the term if not the conception of Virchow was well established in the literature of the subject. Michel, indeed, who published in 1876 the first[4] extended work of modern date on the diseases of the nasal cavity, does not, so far as I can see from the translation of Shurley, speak of the polypi as myxomatous, and his conception of their etiology and pathogenesis does not coincide with the view of their being a new growth of tissue. Cohen, whose work first appeared in 1879, accepted the classification of myxoma. Stoerk, in 1880, did not use the word in connection with them, but in Bosworth's first edition in 1881 they are so referred to. Zuckerkandl[5] very curiously fell into the serious error of Billroth, quoting him with assent in saying they are adenomatous, but he makes no reference to them as myxomatous. Notwithstanding the great value of Zuckerkandl's early work (1882) in intranasal pathology, his histology was lamentably deficient—a criticism which his later edition in 1893 cannot be said entirely to escape, although he modifies his views somewhat as to the adenomatous character of nasal polypi. Beverley Robinson, in his treatise on "Nasal Catarrh," the second edition of which appeared in 1885, refers to nasal polypi as myxomatous. Morell Mackenzie, whose work still remains, after fifteen years, the most indispensable of all the laryngologist's library, begins his chapter on nasal polypi by saying they are new formations nearly always of a myxomatous character.[8] I will not pursue text-book literature into more recent time. Suffice it to say that in nearly all of the special works on the nose this error in nomenclature, if not in conception, still exists.

It is to Hopmann we are indebted for the first serious attempt to dispel it.[9] In 1885 he refuted not only the mistake of Billroth as to their adenomatous nature, but, quoting from the German translation of Mackenzie's book, he denied the latter's assertion as to the myxomatous character of nasal polypi. They are, he asserted, to be looked upon as soft, œdematous fibromata. I have to object in this definition only to the use of the word fibroma, which would indicate a preponderating new growth of fibrous tissue, a condition which does not obtain in the ordinary nasal polyp. While the amount of fibrous tissue varies between *nil* and a condition which might well be given the name of fibroma, the vast majority of polyps consists simply of the normal amount of loose areolar tissue infiltrated and stretched with serous exudate. After I had published,[4] in 1893, a paper on the structure of nasal polypi, being then unfamiliar with the literature of the subject, I received a letter from Chiari, who drew my attention to the fact that in 1887,[6] "on the ground of a histological examination of twenty-three nasal polpyi, polypoid hypertrophies, and papillomata, I came to the conclusion that also in nasal polypi it was only a matter of serous infiltration of the hypertrophy of the mucosa." In many subsequent papers abroad this view has, I think, been incontrovertibly established—most conclusively, I think, by Hajek[6]—and it has been urged in this country by Swain,[7] John Mackenzie,[8] and others.

This return to the former conception of the nasal polyp is the only possible way, and is necessarily a preliminary to the understanding of nearly all the intranasal morbid processes. In numerous publications I have based many observations on this view of it, as have other workers in the same field. Nevertheless in many publications abroad as well as in America nasal polypi are still spoken of as myxomatous.[9] It

[9] The most recent paper dealing with this subject exhaustively is that of Cordes (Arch. f. Lar., Bd. xi., Hft. 2). There is very little to be found in it which has not been stated previously by other observers, but it is a very satisfactory confirmation of much work done by others, the publications of which are scattered through rhinological literature.

seems, therefore, that the error amounts to more than a simple unfortunate phraseology.

I am well aware that this same mistake has been made and the same confusion exists in the pathology of other regions of the body—that myxo is applied to a vast number of tumors which are not myxomatous at all, but simply œdematous. I do not know, however, that it has called such a halt elsewhere to the understanding of pathological processes as it has in the nose. At any rate, with this I am not here concerned. My object in this paper has been to do what I can toward banishing this benumbing idea from nasal pathology, for it is there especially that inflammatory and other pathological changes consist of, or are complicated with, this serous effusion.

An Inquiry into the Rôle of the Domestic Animals in the Causation of Typhoid Fever.—William Royal Stokes describes a series of experiments in which he endeavored to produce infection through the natural route and by natural means by simply allowing the various animals to take in very large quantities of typhoid bacilli in their daily food. Although at least five hundred colonies from the fæces were carefully tested, he was not able to demonstrate the presence of any typhoid bacilli in two chickens, two white rats, two rabbits, two guinea-pigs, one calf, and two pigs. Although he has not employed a large number of animals, he feels justified in expressing the opinion that the typhoid bacillus cannot, as a rule, maintain its struggle for existence in the intestines of the domestic animals. He therefore concludes that the dejecta of animals play no considerable part in the distribution of typhoid fever.—*Maryland Medical Journal*, November, 1900.

Defective Metabolism in Relation to the Mucous Membranes.—H. D'Arcy Power finds a class of patients with various disturbances of the mucous membranes, referable, in his opinion, to defective metabolism. Sometimes the buccal mucosa becomes dry and studded with discrete masses of hypertrophied epithelium. In one case associated gastro-enteric symptoms made it evident that the alimentary canal was similarly affected, as was also the vagina. The patient suffered for three weeks from emaciation due to anorexia, but was cured in three days with benzoate of ammonium. In other cases he finds defective activity of the mucous membranes. One such case has been under his care for several years. All the mucous surfaces are alike affected; the buccal, nasal, and genito-urinary surfaces being always dry, unless stimulated by an occasional catarrh. The condition appears to be congenital and systemic in its origin, not due to a local neurosis. Such general conditions call for remedies of extended activity, and among these pilocarpine in small doses should have a foremost place. It not only increases the general metabolism of the body, as shown by the rise in the excretion of urea, but it specifically affects the mucous membranes and glands. Lastly, he refers to the value of capsicum as a promoter of systemic metabolism, as well as a local stimulant. We know that it increases alimentary leucocytosis, and possibly in this way it affects general nutrition. Its possibilities in this direction are not utilized to the extent they deserve.—*Pacific Medical Journal*, November, 1900.

A Death from Nitrous-Oxide-Gas Anæsthesia.—Thomas C. Evans reports this case. The patient was a girl of five years. The operation was the removal of some large adenoid growths. The child was not well nourished and was a mouth breather. In operations on the mouth, when nitrous oxide is used, a mouth gag is necessary on account of the masseter spasm. In this case, after two or three inhalations the gag became loosened and dropped out of the mouth. The anæsthetic was stopped and the gag replaced. The child was semi-conscious and not at all cyanotic. After two or three inhalations the anæsthetist said that the child was ready for the operation. This consisted in a curettage of the nasopharynx. As the first pass was made with the curette and no hemorrhage occurred, the operation was abandoned and the child was suspended by the heels and artificial respiration begun. Only ninety seconds had elapsed from the first inhalation of the gas. There was no obstruction in the larynx, as the operator's finger was passed into the relaxed trachea. For three-quarters of an hour efforts at resuscitation were continued, but to no avail. Nitroglycerin, strychnine, and also a one-hundred-gallon can of oxygen were prepared. Artificial respiration, inflation, and other means of getting oxygen into the lungs were tried, but there was no attempt on the part of the heart to perform its functions. The pupils were widely dilated. Death was probably due to cardiac paralysis. The child had had measles about a month before the operation and the writer believes that diphtheria followed. This may account for the cardiac paralysis. The amount of gas used was about one-third the quantity usually necessary for the anæsthesia sufficient for such an operation.—*Pediatrics*, December 1, 1900.

Some Atypical Cases of Acute Rheumatism.—G. Miranda reports a number of cases observed on the ship *Fieramosca*. It was characterized by the sudden appearance of œdematous swelling and redness on the dorsum of the foot and around the ankle, accompanied by pain on pressure, and sometimes by spontaneous pain, which was not communicated to any of the adjacent articulations. Sometimes œdema was the only symptom present, but in many cases a more intense form followed, the articulations, however, not becoming involved. Treatment, which consisted of the internal administration of somewhat large doses of preparations of salicylic acid and local applications of ichthyol ointment and salicylic acid, was in every case successful. The rheumatic trouble was accompanied by tonsillitis, acute coryza, and visceral disturbances in the majority of cases, or at the very least by redness and burning in the pharynx, and troubles of deglutition.—*Annali di Medicina Navale*, November-December, 1900.

Section of the Posterior Spinal Roots for the Relief of Pain in a Case of Neuritis of the Brachial Plexus.—Morton Prince describes the case of a man who had paralysis of almost the entire left upper limb, as the result of neuritis following an accident. Division of the posterior roots of the fifth, sixth, and seventh cervical nerves on the left side was performed on account of intense and persisting pain in the thumb and forefinger and corresponding half of the middle finger, back and front; and of less intense pain extending like a half bracelet around the back of the wrist, and from the middle point of this bracelet up the middle of the forearm to the olecranon. The operation gave complete relief from this pain in the upper left limb, but caused Brown-Séquard's paralysis, the motor weakness being on the left side. This paralysis was probably due to hemorrhage within the spinal canal or pressure from granulation tissue or callus. Pain, lasting some months, developed in the neck after the operation, and was probably from an injury to a nerve in the part. The palmar surface of fore and middle fingers was not anæsthetic. The absolute anæsthetic strip along the radial edge of the forearm was probably in part or wholly due to the division of the fifth root. A remarkable partial

restoration of sensation in the anæsthetic area was attributed to overlapping nerve supply from adjoining root areas.—*The Journal of Nervous and Mental Disease*, December, 1900.

The Treatment of Senile Pruritus.—Arthur Jaenicke's method of relieving this obstinate affection, which always tries the patience of both patient and physician, is to brush the affected portion of skin with a soft brush till a plentiful desquamation of the epithelium has been produced. At first this is repeated three times a day for four to five days, after which time the material which can be brushed away is very small in amount, and the frequency of the treatment may be correspondingly diminished. Longer than two days should not, however, be allowed to elapse between successive brushings; bathing is also sure to be followed by a relapse.—*Centralblatt für innere Medicin*, December 1, 1900.

Three Varieties of Membranous Anginas Produced by Microorganisms Other than the Klebs-Loeffler Bacillus and their Sanitary Significance.—William G. Bissell draws the following conclusions from the cases he reports: (1) The streptococcus pyogenes and the micrococcus of sputum septicæmia can produce membranous anginas, accompanied by physical disturbances sufficient to result in death. (2) The oidium albicans produces pseudo-membranous exudates easily mistaken for a Klebs-Loeffler inflammation. (3) The only positive means of determining a Klebs-Loeffler infection is by microscopic methods. (4) From the sanitary standpoint, as regards quarantine, anginas due to the streptococcus pyogenes, micrococcus of sputum septicæmia, and the oidium albicans, require little consideration.—*Buffalo Medical Journal*, December, 1900.

Casts without Albumin and Catarrhal Nephritis.—In a series of twenty-three consecutive cases L. L. Skelton found casts without albumin in twelve. Three were of cirrhosis of the kidney, and albumin had been present at a previous stage of the disease. In the remaining nine the casts were mostly catarrhal in character, a few hyaline casts and an occasional granular cast being present. All of these cases failed to give any history of albuminuria, and none was found on examination. Skelton regards such casts as the expression of an irritated kidney—a kidney making an effort to rid itself of irritating material and being unequal to the task, a catarrhal inflammation being the result. Such irritants may include the various salts of the urine, products of intestinal fermentation, toxins of various constitutional fevers, sugar, bile, pus from the lower portion of the genito-urinary tract, and cases of uncompensated heart diseases, when the failure in the circulation has not reached the stage accompanied by physical signs. In hepatic obstruction to the circulation and in abdominal tumors, the failure of circulation is the cause of the catarrhal nephritis and precedes and merges into cyanotic induration.—*Chicago Clinic*, November, 1900.

Clinical Considerations upon Chancre and Cancer.—Charles Warrenne Allen states that not only do patients now and then present themselves with a primary specific granuloma of the lip in the belief that they are suffering from beginning cancer which they know to be not uncommon in this situation, but it unfortunately happens from time to time that surgeons are led to operate upon this, as well as upon other forms of syphilis here located, in the belief that they are removing malignant growths. The clinical features are at times so similar that a period of observation becomes necessary in order to obviate mistake. They possess in common the feature of occurring with greater frequency upon the lower than upon the upper lip, and in his own experience are both more frequent in men than in women, though statistics are given by some observers to show that women suffer from lip chancre more often than do men. Age is a factor in distinguishing from epithelioma, but not an important one. Still, generally speaking, chancre occurs in youth and cancer in old age. The chancre is much more rapid in its development and the involvement of neighboring lymph nodes is much more prompt, more pronounced, and more painful or tender, though not more persistent. If, as not infrequently happens, the chancre is not indurated at the base, the question of cancer may not arise, although it is possible for a beginning cancer to be quite soft. In a chancre of the lip remaining soft throughout its course the neighboring lymph nodes beneath the jaw are quite as firm as in the indurated form.—*The Post-Graduate*, December, 1900.

Paroxysmal Delirium: a Short Study in Auto-infection.—W. C. Hollopeter reports a series of cases in which the following points are brought out: First, the fever incident to intestinal auto-intoxication has no classified train of symptoms, varying in intensity and regularity according to the nervous mechanism and heredity of the child. Second, the symptoms manifested by auto-intoxication affect the nervous system so variously that it is a question whether a classification by reason of localizing the seat of intestinal irritation can ever be brought about. Third, the symptoms manifested by intestinal ptomains frequently express themselves in symptoms suggestive of typhoid fever, meningitis, and malarial fever, so frequently that without differential diagnosis many cases are thus treated.—*International Medical Magazine*, December, 1900.

The Use of Suprarenal Extract in Diseases of the Middle Ear.—L. S. Somers has found that excellent results may be obtained in acute catarrhal otitis with congestion of the membrane, but without perforation, by the use of suprarenal both in the canal and freely sprayed over the nasopharynx, the tubal opening becoming pervious when it had before resisted treatment, and rapid drainage of the catarrhal secretion in the middle ear took place. In chronic cases, in which sclerosis of the lining mucosa is marked and the ossicles are rigid from fibrous adhesions, the results have been unsatisfactory, not any of his cases responding to the usual good effects of the drug. Of course, this can be readily understood from the physiological action of the suprarenal, and in this class of ear affections it is not indicated unless there be some temporary congestion, which it will remove.—*Therapeutic Gazette*, December 15, 1900.

A Case of Cerebral Tumor with Psycho-Paralysis.—M. Devic and Charles Gauthier report the case of a woman in whom, at autopsy, was found a glioma situated in the posterior half of the left frontal and the anterior portion of the temporal and sphenoidal lobes. The development of this tumor may be divided into two periods: the first, which lasted about six months, was characterized by psychic phenomena—progressive mental impairment, loss of memory, increasing difficulty in understanding and in expressing herself, an attack of ambulatory automatism; the second stage lasted six weeks, and was characterized by an increase in the psychic symptoms, with right hemiplegia with aphasia, and, toward the last, cephalalgia and vomiting. Diagnosis was impossible in the first period, difficult in the second. The authors give at length their reasons for the diagnosis of glioma, which was verified at the autopsy.—*Archives générales de médecine*, December, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, January 26, 1901.

THE TREATMENT OF PULMONARY TUBERCULOSIS IN HOSPITALS AND AMONG THE POOR.

WHILE acknowledging the importance of sanatoria for the treatment of pulmonary tuberculosis and the successful results therein obtained, Burghart (*Berliner klinische Wochenschrift*, 1900, Nos. 27 and 28) pointed out, in a recent address, that such establishments are as yet not sufficiently numerous for the reception even of all cases in which improvement to the degree of economic recovery is possible within a reasonable time. Besides, there are some patients who are unable to enter such institutions because they cannot afford to give up their work or will not submit to separation from their families, or because the prejudice of the family prevails over the decision of the physician and the patient. There are, thus, a large number of cases of tuberculosis of hopeful prognosis that will require the care and the treatment of the practitioner in hospital and in private. In more advanced cases in which recovery cannot reasonably be hoped for, treatment will be required for special symptoms, and a summary of the measures employed at the first medical clinic of the University of Berlin is given by Burghart.

When fever is present in a case in which noteworthy improvement is likely to take place, the patient should, if possible, be kept in bed until the febrile manifestations have remained in abeyance for several days. Should febrile elevation of temperature take place on arising or on walking about, the activity should be restricted or even be interdicted for a few days. In hopeless cases the treatment should be less rigorous, and everything should be done that will mitigate the severity of the symptoms and sustain the courage of the patient. Accordingly, he may be permitted to get out of bed, as cough, pain, sweats, and the sense of weakness and malaise are often thereby lessened. Should simple rest in bed not suffice for the control of the fever, sponging with cool water in the evening or even also during the day may be practised. Antipyretics should be avoided if possible, but in severe cases pyramidon, quinine, or phenacetin may be employed in hourly doses of gr. iss. until five doses are taken.

Slight and occasional sweating will require no treatment, especially if it occur only during the day. The profuse colliquative sweats, especially at night, however, demand therapeutic intervention. Internal remedies are employed only if unavoidably necessary, and of these camphoric acid is to be preferred. Cool sponging in the evening with simple or with aromatic vinegar or with water diluted with citric acid or with alcoholic solutions, often yields satisfactory results. A solution of menthol and alcohol (one or two per cent.) has recently been recommended for this purpose. A small amount of alcohol given at night will frequently control sweating. Sage-tea, taken cold, sometimes has a similar effect. Formalin-alcohol (ten per cent.), with the addition of three or four per cent. of oil of peppermint, may also be employed, being applied to small areas of the trunk at a time.

Diarrhœa is sometimes due to the unaccustomed use of milk, to errors in diet, or to exposure to cold, and it may yield to the withdrawal of milk, correction of the diet, and administration of mucilaginous drinks, such as strained oatmeal, barley water, or even cocoa or bilberry wine. Mutton broth exerts a favorable influence, and scraped meat is constipating. Hot poultices or inunctions with warm oil or applications of cotton to the abdomen are simple and useful domestic remedies. Should drugs be required, resort may be had to decoctions of salep, small doses of bismuth alone or together with extract of opium, tannalbin, tannigen, dermatol, or a few drops of tincture of opium. If rectal tenesmus be distressing, suppositories containing gr. ¾ of extract of opium may be employed. Should the diarrhœa be due to tuberculosis of the bowel or to amyloid degeneration, more powerful agents will be required, such as creosote, inunctions of creosote-vasogen, and starch enemata.

Pain of sufficient intensity to affect the general condition should be relieved, if possible, by hot poultices or inunctions of warm oil or a mustard plaster. Local pain, particularly of the pleura, may be relieved by fixation of the painful area by overlapping strips of adhesive plaster, or a flannel bandage, or a specially made jacket of felt. Under other circumstances resort will have to be had to drugs, such as dionin, opium, morphine.

In the event of hemorrhage the patient should be kept cool and quiet, both physically and mentally, and be given bland food in not excessive amounts. Inquiry into the history and physical examination should be deferred. An ice bag may be placed over the suspected seat of hemorrhage or over the heart. The movements and activities of the patient should be restricted as fully as possible. Food should be given in small amounts frequently, and a minimum of fluid should be permitted. To aid in securing tranquillity small doses of narcotics may be given, as, for instance, gr. $\frac{1}{12}$ morphine subcutaneously. Among drugs employed as hæmostatics, hydrastis, ergotin or ergot, lead acetate, with or without a small amount of opium, may be administered. Subcutaneous injections of gelatin (one per cent. in one per-cent. saline solution) have recently been recommended for the control of hæmoptysis. If the hemorrhage has been profuse, subcutaneous infusions of from 200 to 300 c.c. of from one-and-one-half to two-per-cent. solution of sodium chloride

will be indicated, and if necessary they should be repeated.

In the prophylaxis especial care should be given to the treatment of bronchitis, pleurisy, pneumonia, and such other diseases as predispose to the development of pulmonary tuberculosis. Association with patients suffering from this disease should particularly be avoided. In those with a tendency to catarrhal disorders the bodily resistance should, so far as possible, be increased, and efforts in this direction may in many instances be begun in childhood. Especial attention should be given to the relief of scrofulosis and chlorosis. Excessive indulgence in alcohol is to be avoided in the presence of tuberculosis. The air to which the tuberculous patient is exposed should be pure and free from dust or moisture, and if possible a life in the open air should be pursued. Domestic and personal cleanliness must, of course, be observed. Adequate sleep should be secured, and to this end palpitation of the heart and nervous irritability may require cold affusions or packs, or cool sponging at night, or application of an ice-bag to the precordium, the administration of tincture of valerian or bromide, or even trional. During the day inhalations of camomile tea, at times expectorants, together with discipline, will be required to allay cough. During the night inhalation of Ems salt may be practised, and if necessary small doses of codeine or morphine be administered. Irritative cough due to laryngeal involvement will require local treatment.

The diet should preferably be a mixed one. Amply nutritious food should not be given too frequently. Cane sugar or beet sugar in daily amounts of from ʒ iii. to v. may often be given with advantage when other foods cannot be taken in sufficient quantity. The appetite should be sustained in part by moral suasion, in part by the palatability of the food, and by the use of acid foods or hydrochloric acid and pepsin or bitters before meals. Creosote is of service in the same direction. Removal from home to a hospital may also have a good effect. Small doses of alcohol are useful occasionally as a stimulant.

All accessible tuberculous lesions should receive local treatment. With this object in view agents may be employed by inhalation for astringent purposes (tannic acid), or to liquefy mucus or allay irritation (Ems salt, sodium bicarbonate, ammonium bicarbonate, oil of peppermint, camomile-tea, etc.), or for ozonizing purposes (turpentine), or for caustic purposes (lactic acid, from one-half to one per cent.). Inhalations thrice daily for from fifteen minutes to two hours of watery solutions of formalin (from one-fourth to two per cent.) dropped on gauze, together with gtt. v. of oil of peppermint, may also be practised with advantage. Tuberculin, tuberculocidin, antiphthisin, and the serum of Maragliano have not received general acceptance and application, nor has the use of hetol (sodium cinnamate) become popular, while pulmonary juice and glandulen have not yet established themselves.

Of other remedies that have been recommended creosote is the most serviceable. As a result of its administration appetite is improved, peristalsis is stimulated, the gastro-intestinal contents are disinfected, and possibly the toxicity of the tubercle bacilli is diminished. Creosote has further a disinfecting influence upon the other bacteria in the lungs. Its use renders possible the ingestion of increased amounts of food and its better digestion, and thus favors the nutritive conditions, diminishes morbid secretion, and deprives the tubercle bacillus of its adjuvants. Creosote itself may be employed, or guaiacol, or the carbonate, valerianate, or acetate of either. The initial dose may be small, but the amount should be gradually increased to the point of tolerance. Creosote should not be introduced into the empty stomach or in concentrated form. It may conveniently be given in the form of gelatin-coated or sugar-coated pills or in gelatin capsules; and to the latter a small amount of cod-liver oil may at times be serviceably added. Should creosote disagree, or should it become necessary to intermit its administration for a time for any reason, it may be combined with vasogen and be painted upon the surface.

THE INFLUENCE OF THE SPLEEN UPON PANCREATIC DIGESTION OF PROTEIDS.

Although it is believed that, in addition to its hæmolytic and hæmogenetic functions, the spleen takes some part in proteid metabolism, knowledge on this point is not so clear or so full as it might be. In spite, however, of the important rôle played by this organ in the human economy, its presence is not absolutely essential to the continuance of life, as its successful removal in numerous instances demonstrates. Probably we have here an exhibition of vicariousness of function, the duties of the extirpated organ being assumed by other tissues of cognate activity, *e.g.*, the lymph glands and the bone marrow. It does appear, however, that the results of certain studies by two distinguished Swiss physiologists, Schiff and Herzen, demonstrating the functional relations between the spleen and the pancreas, are not so generally known as they should be. These are considered in a recent communication by H. F. Bellamy (*Lancet*, October 27, 1900, p. 1185).

It has been shown experimentally in dogs that there occurs for a certain time during full digestion a constant rise to maximum digestive power of the pancreatic juice, which is succeeded by an equally constant fall to minimum. The maximum is attained during the eighth hour after the ingestion of a meal, the minimum from the thirteenth to the eighteenth hour. In fasting animals, on the other hand, the pancreatic juice possesses little or no peptonizing power. Further, the spleen becomes enlarged four or five hours after a meal, subsequently to return to its normal size. Now it has been found, on careful experimentation on animals, that the tryptic activity of the pancreatic juice is much less pronounced in animals from which the spleen had been removed or the organ was ligated at its hilus. The conclusion was, therefore, reached that in the presence of the congestion of the spleen that takes place during active digestion, some sub-

stance is produced in the organ that confers upon the pancreas the power of forming its peptonizing ferment.

At a later period it was shown that the digestive glands produced zymogens, which in due process of physiological activity are transformed into the enzymes or ferments proper. It was then suggested that the formation of the supposititious substance generated by the spleen, or internal secretion, consists in this transformation of the zymogen of the pancreas—that is, the conversion of trypsinogen into trypsin. That this is so, was demonstrated by adding to an infusion of pancreas from a fasting animal—containing, therefore, zymogen in abundance and but little ferment—an infusion of spleen from an animal at the height of digestion, with the result that trypsin developed in large amou..t; while corresponding digestive activity was not exhibited by either infusion alone. That this result is not due to oxygenation was shown by the fact that it was not brought about when blood from an indifferent artery or vein ór of the splenic artery of a fasting animal was used, instead of the splenic infusion, although it did occur in a slight degree both when blood from the splenic vein of a fasting animal and when blood from an indifferent artery or vein, as the splenic artery, of a digesting animal was used; but in most pronounced degree when the blood from the splenic vein of a digesting animal was employed.

To compensate for the nutritive deficiency that would be entailed by loss of the internal secretion of the spleen and its influence on peptic digestion, spleenless animals, it has been found, require a larger amount of food than normal animals, increased stimulation of digestive activity being, among other effects, brought about in this way.

RELATIVE MERITS OF SLOW SAND AND MECHANICAL FILTRATION.

The fact that efficient filtration is the only true safeguard against typhoid fever is being slowly but surely borne in upon the minds of the American public. As to the best system of filtration, opinions vary in this country; up to the present, mechanical filtration has held sway. However, it would now appear that this mode of cleansing water of deleterious matter has been weighed in the balance and found wanting. Certain it is that in European cities and in American cities in which sand filtration has been established the mortality from typhoid fever has decreased rapidly. The initial cost of slow sand filtration is more than that of mechanical, but probably this is counterbalanced by the greater working expense of the latter method and by the quicker deterioration of plant. Mr. Gallinger has recently presented in the senate the report made by a special committee of the Medical Society of the District of Columbia upon the relative merits of slow sand and mechanical filtration, which contains valuable information on the subject. It is shown that, putting aside the economical merits of the question, the relative aspect of the two systems, viewed from the standpoint of public health, slow sand filtration exhibits an undoubted superiority. It appears that mechanical filters have accomplished little in reducing typhoid-fever death rates. The mortality rates from this disease are compared between five American cities using the mechanical devices, and five cities in Europe using water from sand filters. The results are as follows: Europe—Berlin, 5 per 100,000; Breslau, 9 per 100,000; Hamburg, 9 per 100,000; Rotterdam, 2 per 100,000; The Hague, 5 per 100,000; average, 6 per 100,000. United States—Davenport, 26 per 100,000; Atlanta, 43 per 100,000; Chattanooga, 48 per 100,000; Quincy, Ill., 58 per 100,000; Knoxville, 59 per 100,000; average, 46.8. That is, the American rate was almost eight times as great as the foreign rate. Concerning the comparative bacterial efficiency of the systems, the report says difficulty has been experienced by some in reconciling the comparatively slight failure of the mechanical filter in bacterial efficiency with its marked failure in diminishing the prevalence of typhoid fever, but by experiments made with water from the Potomac filtered by both methods the sand filter easily demonstrated its superiority in getting rid of bacteria. At the annual convention of the American Society of Civil Engineers held on July 3 and 5, 1900, Dr. Ad. Kemna (Antwerp, Belgium) said in part: "The action of sand filtration is essentially a biological one. The mechanical action of straining is obvious; but as microbes are smaller than the interstices between the grains, this action alone does not account for their retention, and it is absolutely inadequate for the reduction of the dissolved organic matter. Various theories have been proposed. The one which considers reduction as a fermentation is consistent with the greatest number and the greatest variety of facts. . . The fact should be emphasized that sand filtration is not an artificial or theoretical process; that it is a natural process, especially because that process is exactly like what goes on in the purification of streams, which invalidates the sentimental argument against purified river water." Mr. Walter Hunt, engineering director of the Grand Junction Water Works Company, London, England, which use sand filters, at the same meeting spoke as follows: "After all, the greatest testimony as to the quality of any water is found in the statistics in regard to the health of the community supplied. The admirable way in which the water supply of London is conducted, for instance, can be so shown. When the death rate in the metropolis is, as it was a week or two ago, something between 12 and 13 per 1,000, and when the average for the year continues from year to year to be something between 17 and 19, and when, too, the very small amount of typhoid fever which we have in this enormous city is noticed, the inference that the filtration of water is carried out in a very admirable way, and that the community has no need to fear in regard to the quality of that water, seems fully justified. We are able to deal with it absolutely well by sand filtration, taking out something like from 98.99 per cent. or 99.999 per cent. of the microbes, and the chemical analyses as made by Sir William Crookes and Professor Dewar, and also by the government analyst,

Dr. Thorpe, are most satisfactory." Sand filtration has been proved in instance upon instance to be effective in checking the spread of typhoid, and, after all, this is the most convincing testimonial to its merits. Its primary cost is greater and it requires more space; but, on the other hand, mechanical filtration is more expensive to operate and requires the greatest care in the artificial chemical processes which constitute the system. Sand filtration is a natural process and has given better practical results than any form of mechanical filtration yet in vogue.

COFFEE DRINKING IN THE UNITED STATES.

The use of coffee in the United States has attained enormous proportions and so long as it is not consumed to excess its universal consumption is a healthy sign. At any rate, the habit is preferable to that of alcohol; but, as with alcohol, the bounds of discretion may be passed, and when this occurs coffee may and often does exert extremely deleterious effects. In the Medical Record, January 12th, Dr. Leszynsky reviews the subject from this standpoint, and shows where coffee is useful and where it is harmful. It is pointed out that caffeine, to which is due the larger part of the physiological action of coffee, is an absolute poison to some persons, while on others no injurious effect whatever would seem to be produced. The former class are of the neurasthenic type. The advice is wisely offered that coffee should never be given to young children. With regard to the symptoms of acute and chronic coffee poisoning, Dr. Leszynsky remarks that between these conditions there is a peculiar difference. In the former, when coffee is taken in large doses by persons unaccustomed to its use, it produces excitability to the degree of delirium, etc. In the latter, which is of greater importance on account of its more frequent occurrence, the toxæmia manifests itself as a depressive form of neurasthenia. In brief, the symptoms of chronic coffeeism are indicative of interference with the nutrition of the cells of the cerebro-spinal system resulting from overstimulation and auto-toxæmia, and correspond very closely with the symptoms of chronic alcoholism, for which it is often mistaken. The fact is undoubted that coffee has an injurious effect upon many people, and it is also as undoubted a truth that excessive indulgence in the beverage so loved of our European ancestors does good to no one. At the same time it is to be hoped that coffeeism may not become prevalent among Americans and that its toxic effects have been somewhat exaggerated. The habit which is followed by some persons in this country of drinking two or three cups of coffee at lunch or dinner when eating meat is greatly to be deprecated, as it must, in the nature of things, disturb digestion and will, if persisted in, permanently weaken the digestive powers. Coffee, partaken of judiciously, is an excellent form of liquid refreshment; but we would add the saving clause, that it must be of good quality and properly made: the latter being almost an art in itself.

KOCH ON MALARIA AND BLACKWATER FEVER.

Professor Koch has recently made some noteworthy pronouncements on the origin of malaria and the most efficient mode of treatment, which, albeit somewhat belated, will be listened to with great respect. He declared that he was convinced the mosquito acted as the intermediate host of the malarial-fever germ and that the only specific for that complaint was quinine. It is to be regretted, however, that in making this statement he seems to have quite ignored the researches and conclusions of the Italians, Bignami and Celli; and, above all, those of Manson and Ross. To a person who was unacquainted with the subject it would appear that Dr. Koch was propounding original views. However, it must be satisfactory to all concerned, and especially to Ross and Manson, that their work has received the seal of approval from so distinguished an investigator as the German scientist undoubtedly is. Another conclusion reached by Dr. Koch, that quinine is the cause of blackwater fever, has been received not only with scepticism by those physicians who have had experience in tropical diseases, but in the case of many with absoluted disbelief. Dr. Manson said a short time ago that Koch's view of the quinine origin of blackwater fever was altogether untenable; that blackwater fever was an intense form of malaria was not borne out by facts—the infection was usually a mild one. He thought the idea that it was due to a special type of malaria parasite, possibly resulting from passing through a special form of mosquito, or that it was a disease sui generis as had been held, was not improbable. The *Indian Medical Gazette* of a recent date says that Dr. Nuttall, of Cambridge, some time ago sent to the editor of the *Deutsche medicinische Wochenschrift* a criticism of Koch's which was refused publication in his absence. The Indian journal goes on to say that Professor Koch seems to be regarded in Germany as a sort of medical Kaiser whom to criticise is "lèse majesté."

THE GREATEST ADVANCE IN SCIENCE IN THE NINETEENTH CENTURY.

The *London Spectator* says that there can be little doubt that nine men out of ten if asked what was the greatest idea which science had introduced into the world in the nineteenth century would answer "evolution." On the whole, we think they would be right. Darwin holds in the scientific world of the ninteenth century the place which Newton had taken in the seventeenth; with a patience and an insight conjoined only once in an age, he gave a clear and persuasive account of the way in which one step in the great world process of evolution might have come about. The nineteenth century will ever be remembered as the age which established the doctrine of evolution, and Englishmen will be justifiably proud to think it will be coupled to all time with the name of Darwin. When evolution is mentioned three other names will immediately occur to one's mind, those of Huxley, of

Spencer, and of Wallace. The publication recently of the "Life of Huxley" has aroused fresh interest in that philosopher, and, considering that he was a member of the medical profession, interest in him and his doings will partake of a somewhat personal nature. If it had not been for Huxley's unceasing labors in spreading abroad the Darwinian theory it is more than likely that evolution would have fallen flat or at any rate would not have attracted the attention of the general public so quickly and so widely as it has.

By some Huxley was known as the "great apostle of evoluton"; he termed himself Darwin's bulldog, and right ably did he perform bulldog work in exhibiting and making clear to the man in the street the true interpretation of the "origin of species." For long he had to contend against religious prejudices, and his famous discussion with the late Bishop Wilberforce will not be soon forgotten. The bishop, who was the most witty and eloquent English churchman of his time and who was commonly known by the not altogether complimentary sobriquet of "Soapy Sam," jeered Huxley for endeavoring to propagate so absurd an idea as that of evolution and wished to know whether it was through his grandfather or his grandmother that he claimed his descent from a monkey, to which Huxley retorted, "I asserted and I repeat that a man has no reason to be ashamed of having an ape for his grandfather. If there were an ancestor whom I should feel shame in recalling, it would rather be a man—a man of restless and versatile intellect—who, not content with an equivocal success in his own sphere of activity, plunges into scientific questions with which he has no real acquaintance, only to obscure them by a nameless rhetoric and distract the attention of his hearers by eloquent digressions and skilled appeals to religious prejudice." The verdict of posterity upon both Darwin and Huxley among thinking men, irrespective of their theological convictions, will assuredly be that they were scientists of the very first rank who shed lustre on the nineteenth century.

STATE ENDOWMENT FOR THE ADVANCEMENT OF MEDICAL SCIENCE.

In the *International Monthly*, May, 1900, is a forceful plea by Dr. D. B. St. John Roosa urging state endowment for the advancement of medical science. The history of the rise and development of medical teaching in New York is briefly sketched, and it is shown that up to comparatively recent times all the medical colleges have resembled joint stock companies rather than independent teaching institutions. The alteration which has been effected in the constitution of medical colleges, it need hardly be said, has been productive of nothing but good. As Dr. Roosa remarks, this is one step forward, but he argues that the universities and colleges which now have the complete control of the medical teaching cannot, from their own funds or from private gifts, properly equip them. In the first instance, every medical school should be connected with a hospital of a size sufficiently large to provide ample material for clinical instruction, and the time is coming when the public at large will appreciate this. Next, and as important, is the necessity for a laboratory. The reason why Germany and France have been so prominent within the past thirty years in scientific research is not because of the superior ability or the more enduring patience and perseverance of their students, but because of the especial opportunities for pursuing investigations provided by a paternal and far-seeing government. In order to diagnose correctly various obscure diseases, trained men are needed. This training can be acquired only by a long experience in laboratory work. But a properly equipped laboratory involves the expenditure of much money. According to Dr. Roosa, two kinds of laboratories are required: one such as that in the Pasteur Institute in Paris, and one like the Koch Laboratory in Berlin. He further contends that the State ought to provide sufficient funds for the adequate and thorough instruction of all the pupils in every medical institution already legally authorized and for such others as the increase of population may cause to be established under the regulation of the State. If this were brought to pass —and in a country so rich as America the difficulties in the way should be easily overcome—there is every reason to predict that American medical men would successfully compete with those of Europe in the investigation of disease and the saving of human life.

THE ILLNESS AND DEATH OF QUEEN VICTORIA.

The illness and death of Queen Victoria, in which so much interest has been manifested regarding relations of cause and effect, have been explained by the occurrence of two attacks of arterial thrombosis of the brain; one following the other at short intervals. The first seizure, accompanied with incomplete hemiplegia, was on January 16th, and the last, with increase of paralytic symptoms, a few days before the fatal issue.

From a pathological view the case followed a very ordinary course. It appears quite probable that the primary lesion was the parietal form of embolism consisting of adhesion of portions of the clot to the inner wall of the vessel, merely obstructing the blood current, and that afterward there was complete obliteration of the affected vessel by the formation of increased coagulum. All this is consistent with the symptoms of the malady as thus far detailed.

The somnolent condition which antedated the more pronounced symptoms of trouble was evidently due to sluggish cerebral circulation, and was the beginning of the end. It is well known that mental torpor in elderly patients is a common precursor of the brain lesion in question, inasmuch as a slow blood current invites the deposit of coagulum on the already roughened and atheromatous walls of the cerebral arteries.

If the reports as published are strictly correct—to the effect that hemiplegia was complete—it is easy to believe that a large portion of the motor area of the brain was involved in the lesion; especially did this appear to be the case in the final seizure.

It is quite probable also that a hemorrhagic infarction occurred at that time, inasmuch as the conditions of the original area of deficient blood supply gave ample opportunities for such a mishap. In fact, it is not unusual under such circumstances for the extravasation to become extensive enough to give rise to all the symptoms of profound apoplexy.

Although the distinguished patient was the fortunate possessor of a strong constitution, there was no guarantee against the degenerative tissue changes which occur to all elderly personages. While these metamorphoses go on almost simultaneously in all the vital centres, there is generally some specially weak spot in the organism which gives way first. Commonly, as in this case, it is the brain, which amply accounts for the frequency of apoplexy, cerebral thrombosis and embolism in the aged.

News of the Week.

The Women's Medical Association of New York City.—The Alumnæ Association of the Woman's Medical College of the New York Infirmary for Women and Children has, in view of the closing of the Woman's Medical College of the New York Infirmary, and the impossibility of new alumnæ entering the association, undergone certain changes of name and objects. It was deemed advisable to make the society a living force by adopting its present more comprehensive name, and making women physicians, graduates of regular schools at home and abroad, eligible to active membership. The president of the association is Dr. Elizabeth M. Cushier, and the secretary, Dr. Evelyn Garrigue, 18 West 103d Street.

Philadelphia County Medical Society.—At a stated meeting held January 9th, Drs. John H. Musser and A. O. J. Kelly read a paper entitled "Hæmoglobinuria Complicating Typhoid Fever" and related a case presenting this rare complication. Dr. William Osler, of the Johns Hopkins University, read a paper entitled "Perforation and Perforative Peritonitis in Typhoid Fever," in the course of which he made an earnest plea for a thorough study of the symptoms of this condition, in order that an early diagnosis may be made, and delay in operation may be avoided. At a stated business meeting held January 16th the following officers were elected for the ensuing year: *President*, Dr. George Erety Shoemaker; *First Vice-President*, Dr. Thomas H. Fenton; *Second Vice-President*, Dr. Francis Perkins; *Secretary*, Dr. Ellwood R. Kirby; *Assistant Secretary*, Dr. William S. Wray; *Treasurer*, Dr. Collier L. Bower; *Censor*, Dr. Frederick P. Henry. Reports of the directors, of the treasurer, of the censors, and of the publication committee were read.

Stony Wolde Sanatorium.—Having observed the lack of proper sanatoria for the care of working women and children suffering from tuberculosis, a number of ladies interested in charity formed a committee last September for the purpose of establishing the Stony Wolde Sanatorium. The officers of this committee are Mrs. George F. Shrady, chairman; Miss Gertrude Gold Shipman, secretary; Mrs. James Edward Newcomb, treasurer. The site now under consideration for this sanatorium is at Kushaqua Lake, on the Adirondack division of the New York Central and Hudson River Railroad. It consists of five hundred acres, has excellent water facilities, and is claimed to be ideal in nearly every particular. The sanatorium will be built on the cottage plan and the number of cottages erected will depend upon the amount of money subscribed. It is hoped that accommodations may be provided for one hundred patients. In the past three months there have been twenty-four applications for treatment in this sanatorium. All of these applicants were in the incipient stages of tuberculosis. The institution will be non-sectarian and under the control of the following board: Dr. Edward G. Janeway, Dr. Francis Delafield, Dr. George F. Shrady, Dr. Charles H. Knight, Dr. Charles M. Cauldwell, Dr. Arthur G. Root, Albany; Dr. Henry Hun, Albany, and Dr. James E. Newcomb.

Dr. Mary Moore Wolfe has been elected resident physician in the department for women of the Pennsylvania State Hospital for the Insane at Morristown, in succession to Dr. Susan Taber.

The Manhattan Dermatological Society of New York City.—A society with this name was recently organized in this city. The officers for the first year are: *President*, Dr. William S. Gottheil; *Vice-President*, Dr. Ludwig Weiss; *Secretary*, Dr. Jacob Sobel.

Cold Weather in Cuba.—At the time of the recent cold wave in this part of the country Cuba was visited with a severe "norther" which carried the temperature in all parts of the island to an uncomfortably low degree. This will render the mosquitos more or less quiescent and put an end to the lingering traces of yellow fever in Havana, just in time to make it more pleasant for the members of the Pan-American Medical Congress.

An Evident Misfit.—The Health Officer of the Port of Perth Amboy, N. J., has granted an interview to a reporter of the *Chronicle* of that place, in which he aired some heterodox views concerning vaccination. He said vaccination would not render any one immune against smallpox, and that the operation was putting poison into a person's body, giving him a distinct disease which sometimes caused more suffering than smallpox. He implied that compulsiory vaccination was a crime, yet said he would, in his capacity of health officer, vaccinate every person on any ship which might enter the port with smallpox on board. This remarkable health officer is entitled to hold any opinion concerning the efficacy of vaccination which he may please, but a sense of the fitness of things should lead him to retire from his official position before giving public expression to such misleading and dangerous views.

Twins Born in Different Centuries.—In a small town in Warren County, this State, twins were born, one a few minutes before midnight on December 31,

1900, the other a few minutes past twelve o'clock on the morning of January 1, 1901. The neighbors are quarrelling as to what day shall be celebrated by the couple as their common birthday, or whether the children, being born in different days, months, years, and even centuries, may be regarded as twins, or simply as brothers.

Epidemics in Southern New Jersey.—Many of the towns in the lower part of New Jersey are being ravaged by epidemics of scarlet fever and diphtheria. In numbers of places the schools have been closed, and in some even church-going and other assemblages have been abandoned.

The Smallpox in New York is well under control by the health board and only occasional cases are reported. From the beginning of the outbreak up to January 19th, one hundred and twenty-eight cases of the disease had come to the knowledge of the board of health. Ten of these cases resulted fatally. It was reported by the State board of health at the end of last week that there were seventy-five cases of the disease in this State, the greatest number being in Watertown and Schenectady.

A Druggist Mulcted for a Mistake in Dispensing.—A man of this city who sued a drug firm to recover $2,500 damages and $55 medical expenses incurred in the treatment of his infant daughter, on the ground that on a prescription calling for twelve tablets of calomel there were sold him a dozen strychnine pills, each containing one-twentieth of a grain, recently recovered a verdict of $500 in the Supreme Court. The child is now in perfect health, it was testified.

Insanitary Condition of Sing Sing Prison.—Five members of the State Prison Association, in company with a sanitary engineer, made an inspection of Sing Sing prison last Saturday. They found that the prison buildings are only four feet above tidewater, and that at high tide there is no outlet for the sewers. All the refuse is thrown back into the place, forcing gases into the prison. They condemned all the plumbing. The occurrence of over thirty cases of typhoid fever in the prison was the immediate occasion of the examination.

Jockeying the Doctors.—The profession is warned against a couple of men who, it is thought, are visiting physicians' offices, offering a large sum for the treatment of a jockey connected with a prominent racing stable, but endeavoring on the strength of it to secure among other things an advance in cash from the physician.

Arrested for not Reporting a Case of Smallpox.—A physician has been arrested in Brooklyn on complaint of one of the health officials charging him with having sent a false certificate of death in the case of one of his patients who had died of smallpox. The certificate alleged typhoid fever as the cause of death, and the case had also been reported as such while the patient was under treatment. The accused pleaded not guilty and was paroled for further examination. On the surface it would seem somewhat difficult to prove that the case was one of false certification rather than of faulty diagnosis. The latter is reprehensible, if not inexcusable, but it can hardly be called a crime.

Fire Damages Virchow's Museum.—As a result of a fire occurring in the pathological museum of the University of Berlin, on January 16th, a number of specimens forming a part of the Virchow collection were destroyed or greatly damaged.

The Epidemic of Influenza in this city seems to be, temporarily at least, on the decline, the cold weather having apparently caused its subsidence. During the week ending January 19th, there were eighty-two deaths from influenza, and forty-five in the previous week.

University of Pennsylvania.—Dr. Wm. G. Spiller has been appointed demonstrator of neuropathology and will conduct an elective course for a limited number of graduates and students for the study of the pathology of the central nervous system and the preparation and examination of microscopic sections.

A Plague Ship at Hamburg?—A despatch from Berlin states that the German steamer *Pergamon*, which arrived at Hamburg on January 15th from Smyrna, had a number of dead rats on board. This caused a suspicion that they had died from the bubonic plague. The rats are undergoing bacteriological examination.

Quarantine of the Cook County Hospital.—On orders issued by Commissioner of Health Reynolds, of Chicago, the Cook County Hospital has been quarantined on account of smallpox, no one being permitted to leave or enter it. Several students of the Rush Medical College had examined a smallpox patient, who had presented himself at the college clinic, and then went through the wards of Cook County Hospital. On the same day a man with smallpox visited a friend, who was a patient in the hospital, and remained there some time before the nature of his trouble was discovered. On this account, a despatch from Chicago states, the building will be quarantined until all danger of an outbreak is at an end.

A Curious Case of Sex Concealment.—A person died in this city last week who had always passed as a man of the tougher sort, but who was found on death to be a woman. She was an active politician of a low order, drinking with the "boys," gambling, fighting, and conducting herself in every way like her fellows. She has voted for many years, was married twice, and had an adopted daughter who lived in her house, never suspecting her "father's" sex. The case was as curious in its way as that of an English army surgeon, whose history was related some years ago in the medical journals, who had seen much service at home and abroad, no one having a suspicion that she was not a man.

Arrested for Spitting.—A man named Henry Nearman was held for trial in $100 bail by Magistrate Hogan in the West Side police court on Saturday for expectorating in a Ninth Avenue elevated car. Pend-

ing the trial he was paroled. The complaint against him was made by Mr. Henry W. Hardon, a lawyer, and formerly an instructor in Columbia University, who said that Nearman continued to spit in the car after his atttention had been called to the board-of-health sign prohibiting it. The elevated guard also ordered the offender to desist, but the more he was remonstrated with, the more profusely he expectorated. Complaint was then made to the board of health, and a summons was obtained for the man's arrest. Mr. Hardon is a public-spirited citizen who deserves the thanks of all decent persons for his performance of a disagreeable duty.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy for the week ending January 19, 1901. January 11th.—Assistant Surgeon J. B. Dennis to delay reporting for duty at naval academy until January 21st. Assistant Surgeon J. C. Pryor ordered to duty at naval hospital, New York. January 16th.—Assistant Surgeon R. B. Williams detached from the navy yard, New York, and ordered to the Pensacola navy yard. Assistant Surgeon T. M. Lippitt detached from the naval hospital, Yokohama, Japan, and ordered to the naval hospital, Mare Island, via *Solace*. Assistant Surgeon B. L. Wright detached from the naval hospital, Yokohama, Japan, and ordered to naval hospital, Mare Island, per *Solace*.

College of Physicians of Philadelphia, Section on General Medicine.—At a stated meeting held January 14th, Dr. William G. Spiller exhibited "A Case of Right Facial Palsy Followed by Transitory Paralysis of the Right Upper Limb." The former condition was evidently of peripheral origin, while the latter, which was associated with astereognosis, was believed to be dependent upon a lesion in the left parietal region. Dr. Henry M. Fisher exhibited "A Case of Paralysis of the Infraorbital Division of the Fifth Nerve" inflicted by the prong of a pitch-fork. Dr. Joseph Sailer exhibited "A Case of Arthropathy without Symptoms of Spinal-cord Disease." The patient was a degenerate with general wasting, but with enlargement of both knees, attended with a sense of objective heat. Dr. J. H. Musser was elected chairman for the ensuing year, and Dr. S. McC. Hammill, clerk.

The Late Dr. Horace T. Hanks.—At the annual meeting of the Medical Association of the Greater City of New York, held at the New York Academy of Medicine on January 14, 1901, the following report was presented. P. Brynberg Porter, M.D., *Recording Secretary*.

"The committee appointed by the president, Dr. Weir, at the December meeting of this association, to prepare a suitable minute in regard to the death of Dr. Horace Tracy Hanks, begs leave to report as follows:

"It is with sorrow that we are called upon to report the death of Dr. Horace Tracy Hanks, one of the charter members of our association. Dr. Hanks died of Bright's disease, at his home in this city, on November 18, 1900. He was born in East Randolph, Vt., on June 27, 1837. He was graduated from the Albany Medical College in the class of 1861. After serving as an acting assistant surgeon in the Union army for two years, he began the practice of medicine in Royalston, Mass., where he remained, however, for a short time only—removing to New York City.

"He held many positions of responsibility, among which are the professorship of the diseases of women in the Post-Graduate Medical School and attending surgeon to the Woman's Hospital in the State of New York. He was consulting gynæcologist to the Tarrytown, Mount Vernon, and St. Joseph's hospitals. He was a member of the New York Academy of Medicine, the New York County Medical Society, and the American Medical Association, and was a fellow of the American and of the British Gynæcological societies. (Signed) Henry D. Nicoll, Clement Cleveland, Edward E. Tull, *Committee*."

Obituary Notes.—Dr. Edward L. Pardee died of pneumonia in this city on January 11th. He was born in Romulus, N. Y., in February, 1842, and was graduated from the New York University Medical College in 1870. He was one of the house staff of Charity (now City) Hospital in 1872 and 1873. For twenty-three years he was connected with the board of health of this city, the greater part of the time being chief inspector and manager of the vaccine laboratory. He retired in 1897, and went to East Bloomfield, N. Y., to live. He had come to this city to spend the Christmas holidays and was stricken with grippe, pneumonia rapidly developing.

Dr. Benjamin Brown, of Chicago, died at Washington on January 17th at the age of sixty-three years. He had practised for many years in Chicago and was prominent in Republican politics in that city, but had been ill for a year with the disease from which he died.

Dr. James Boyd McKelvey died at Bloomsburg, Pa., on January 15th at the age of seventy-six years. He was a graduate of Williams College and of the medical department of the University of Pennsylvania.

Dr. Henry Foster, of Clifton Springs, N. Y., died suddenly of heart disease on January 15th. He was born in 1821 and was graduated from the medical department of the Western Reserve University, Cleveland, Ohio, in 1848. He was the founder and proprietor of the Clifton Springs Sanatorium.

Dr. Charles Wesley Purdy died in Chicago on January 20th at the age of fifty-four years. He was born in Kingston, Ontario, and was graduated from the medical department of Queen's University and Royal College of Physicians and Surgeons in 1869. He had practised in Chicago for many years, being especially interested in diseases of the kidneys.

Dr. Lillian R. Safford died in York, Pa., on January 21st. She was a graduate of the Woman's Medical College in this city.

Dr. George Lester Rundle, of Passaic, N. J., was killed on January 21st by a train of the Lackawanna Railroad which struck his carriage as he was driving across the track. He was hurled into a gully beside the track and was carried to the Passaic Hos-

pital, where he died. He was thirty-four years of age and was a graduate of the medical department of the New York University in the class of 1890.

Dr. Charles E. Conrad died in Quincy, Ill., on January 21st, at the age of eighty-one years. He was born in Siberia and studied theology and medicine in Berlin, where he received his medical degree in 1848. He worked in India as a medical missionary for several years, and then came to America, taking up his residence in Quincy.

Progress of Medical Science.

Journal of the American Medical Ass'n, Jan. 19, 1901.

Athrepsia Infantum; Marasmus, or Wasting Disease; Atrophy; Malassimilation of Food.—Louis Fischer states that Parrott was the first to define this disease, and he classified it into three stages: (1) The infant suffers from a simple diarrhœa: the stools are liquid, curdy, often green, and contain an excessive quantity of mucus. The abdomen is distended with gas. Stomatitis appears. The infant is restless and sleepless. The tissues become flabby and wasting commences. (2) The symptoms are intensified. The temperature falls below normal. The wasting is extreme. (3) The third stage brings the child into a moribund state. Death then ensues. By far the greatest number of cases of athrepsia are found in bottle-fed children, though there are many among breast-fed children. The treatment consists in removing the cause. Medication amounts to nothing in the treatment. The blandest and least irritating food must be selected, while frequent weighing of the infants should be resorted to in order to ascertain their progress. When there is much diarrhœa milk must be used sparingly or altogether omitted for a while. Small quantities of whey and barley water, white of egg and barley water, or the juice of a rare chop or steak may be given at short intervals during the day and night. As soon as the diarrhœa begins to improve, milk in some form may be allowed. At times we must resort to various methods of feeding, until we find the proper method upon which a baby will thrive. The writer then takes up the subjects of humanized milk, sterilized milk, pasteurized milk, and peptonized milk.

Angina Epiglottide Anterior.—Clement F. Theisen states that this name was given by Michel in 1878. True angina epiglottidea anterior occurs quite often as a primary affection, and is a separate and distinct condition. There are various tiological factors, such as injury of the lingual tonsil or epiglottis itself, the inhalation of pungent chemical vapors, the swallowing of raw spirits. It is also a possible complication of Ludwig's angina. It may be part of a general œdema of the fauces, or it may occur during the course of certain infectious diseases. It may occur suddenly with perichondritis, carcinoma, or ulcerative processes due to syphilis and tuberculosis. As to the diagnosis, the condition cannot well be mistaken for anything else. The writer urges the employment of the laryngoscope in all cases in which patients complain of severe pain in the throat and inability to swallow, with a normal pharynx. In the treatment, the value of early scarifications is emphasized. An iced ichthyol spray is valuable. In case ice or iced sprays cannot be used, steam inhalations—medicated—would be of service. The conclusions are: (1) Angina piglottidea anterior is very often primary and is an acute infectious process. (2) The term "acute infectious epiglottitis" is suggested for this condition as being more scientific, and more fully explaining its probable nature. It is, of course, understood that the inflammation and œdema involve only the anterior surface of the epiglottis.

The Boston Medical and Surgical Journal, Jan. 17, 1901.

Note on the Treatment of Epidermoid Cancer by Roentgen Rays.—Francis H. Williams says that his experience at the Boston City Hospital indicates that we have either in the *x*-rays themselves or in some other form of radiation from an excited Crookes tube a valuable therapeutic agent in epithelioma, and that the beneficent action of the *x*-rays can be brought about without causing a burn. Foul and nearly unbearable odors cease, the discharge becomes less, and the growth steadily diminishes in size. The earlier this treatment is undertaken the better. It is not improbable that we shall find its curative action limited to superficial growths, though as a means of relieving the painful features of the disease in other forms it may be of some use.

Medical News, January 19, 1901.

Problems in the Etiology, Diagnosis, and Treatment of Tuberculous Disease of the Upper Air Passages.—Jonathan Wright believes that the interesting phenomenon connected with the subject of infection is that apparently the mucous membranes absorb, the lymphoid material harbors, and the lymph channels carry the tubercle bacillus and yet are themselves relatively immune to its morbific influences as compared to the walls of the bronchioles and air vesicles. This, however, is not so much the case with the cervical and bronchial glands. The individual as well as the generic variation of both bacteria and their hosts in the general scheme of the bacterial etiology of disease must be remembered. The lungs are generally the primary seat of the disease. Primary disease of the upper air passages is so rare that its very occurrence has been doubted. The writer emphasizes three points in reference to diagnosis: (1) The diagnosis of incipient laryngeal tuberculosis. (2) The differential diagnosis of tuberculosis from syphilitic laryngitis, and these include the (3) salient point, viz., the microscopic examination of the sputum. (1) Laryngoscopy strengthens or weakens the suspicions concerning the disease, and physical evidences of pulmonary involvement with the laryngoscopic evidence will form a probable diagnosis, but the demonstration of the tubercle bacillus must prove it. (2) A history of syphilis with the characteristic serpiginous ulceration will make the diagnosis easy. Laryngeal stenosis in syphilis may supervene promptly and suddenly. Tuberculous laryngitis is usually not accompanied by dangerous dyspnœa. Syphilitic laryngitis usually is. The observer must be on his guard and beware of the history given by the patient. (3) Sputum analysis should always be carefully made. If the tubercle bacillus is not found, iodide of potassium and mercury should be given till the case is cured or the diagnosis is clear. Climatic change is probably the most effective agent in the cure of the disease. As to the cure of laryngeal tuberculosis by agencies at our disposal in the present stage of our knowledge, honest belief as to that seems to be largely a matter of individual temperament

Ligation of the Internal Jugular Vein followed by Thrombosis of the Lateral and Sigmoid Sinuses.—Charles G. Levison states that removal of malignant growths of the neck is the usual indication for the ligation of the internal jugular, whose ligation greatly facilitates the removal of the growth. Secondary hemorrhage is due to an infection, a factor which can be practically excluded by our modern methods. The writer reports the case of a man aged fifty years, who was operated on for a tumor which extended above to the jaw and almost to the median line. About two inches of the jugular were removed with the growth. The patient died in coma on the sixth day. At autopsy the peripheral end of the vein was obliterated, quite collapsed, and devoid of blood. The distal end was distended by a firm clot. The sinus on the operated sid was distended with blood. Upon opening of the lateral sinus down to the jugular foramen, an organized clot, continuous with the clot in the jugular, was discovered. The sinus on the opposite side and the longitudinal sinus contained only fluid venous blood. Rohrbach's statistics show that this complication subsequent to ligation of the internal jugular is of infrequent occurrence. The indications which he gives for the ligation of the internal jugular are as follows: (1) Hemorrhage due to a laceration or erosion —here the lateral ligature or suture has its place. (2) Tumors involving the vein. (3) Periadenitis due to tuberculous lymphomata closely adherent and inseparable from the vein. (4) Aneurismal varices. (5) Pyæmic otitis, complicated by thrombosis of the lateral sinus.

Conclusions Formed after Six Years' Experience with the Antitoxin Treatment of Diphtheria.—Henry F. Koester concludes: (1) Antitoxin is a positive cure for diphtheria when employed in sufficient quantity and sufficiently early in the disease. (2) Even when employed too late in the disease to produce its specific action, it cannot under any circumstances be productive of harm. (3) When used before the invasion of diphtheria, antitoxin possesses a positive immunizing power which lasts about thirty days. A great deal has been said about the failures of antitoxin, but in none of these cases has it ever been stated what quantity of antitoxin was employed, how early in the disease it was given, what complications existed before use, or how other medication, as for example large doses of bichloride of mercury, may have contributed to the unfortunate ending.

Notes on the Interesting Cases of a Month's Dispensary Practice.—By William L. Stowell.

A Case of Adiposis Dolorosa.—By Ellice M. Alger.

New York Medical Journal, January 19, 1901.

A Case of Paroxysmal Hæmoglobinuria.—W. J. Lamson reports the case. The patient was a man, American, aged forty, who had lived as a child in South America, but had had none of the tropical diseases. One day, after a long drive in the cold and being thoroughly chilled, he passed urine deeply colored with blood. Thereafter he had similar attacks at irregular intervals, and they have continued till the present time, a period of some eight years, always referable apparently to exposure to cold. A typical attack begins about 10 A.M. with a chilly feeling, often becoming a rigor; cold extremities and cyanosis of fingers, nose, and ears; increase in jaundiced hue, and nausea. He then passes urine of port-wine color, somewhat more frequently than normally and in greater amount. The chill lasts from one-half to three hours and is succeeded by a feverish sensation. At times an urticarial eruption appears on the dorsum of the hands or on the right cheek; or he may have tender painful areas over the bridge of nose, around the right orbit, or in the left groin. Normal urine is passed again, sometimes in twenty minutes, often not for several hours, depending on how quickly he becomes thoroughly warm. Between the attacks he feels perfectly well, but is a little anæmic. The blood shows no plasmodia. The urine is normal. There is a double murmur at the base of the heart. No remedial measures have been of any special service. The author gives a general description of the malady, and considers the best therapy to be removal to a climate where the temperature is mild and equable.

A Peculiar Case of Migratory Foreign Body with X-Ray Illustrations.—By D. Braden Kyle. The patient was a woman who complained of frightful neuralgic pain with soreness and swelling. The peculiar feature in the case was the change of site of the symptoms. At times one would almost suspect mastoiditis. Sometimes facial neuralgia, again ethmoiditis, and lastly all the symptoms of confined suppuration of the maxillary sinus were present. During one of these attacks a piece of a needle was discharged from the nostrils in a mass of pus, but symptoms continued at intervals. A radiograph led to a suspicion of a foreign body in the antrum, but nothing was found on exploration through the canine fossa. A few days later a gumboil-like swelling formed near the operative opening, and finally discharged spontaneously; but something hard was located and found to be the rest of the needle, which was easily extracted. Symptoms permanently disappeared.

General Anæsthesia; the Preliminary and After-Treatment with Remarks on Ether and Chloroform.—By E. Payne Palmer. A general article containing nothing new.

Report of Two Cases of Dermoid Cyst of the Nose.—By H. S. Birkett.

Two Cases of Hæmarthrosis of the Knees.—By B. A. Hibbs.

The Method of Examination of Infants.—By C. Herrman.

Gastric Ulcer; Report of Two Cases.—By E. S. Goodhue.

Philadelphia Medical Journal, January 19, 1901.

Two Cases of Localized Neuritis Occurring as a Complication of Typhoid Fever.—H. J. White states that localized neuritis is one of the rarer of the many and widely distributed complications of typhoid fever. Multiple neuritis is much more common. The etiology of the latter is now generally accepted as follows: The toxins produced by the typhoid bacillus act directly on the nerve fibres, causing a mild perineuritis. But the singling out of one nerve or set of nerves which is affected, in the former condition, seems to betoken some special individual susceptibility to the effects of the toxin. The writer then reports two cases. The first was that of a man aged fifty years, who, after an attack of moderately severe typhoid which began about February 1, 1900, showed a double ulnar neuritis. He was admitted to the hospital May 31, 1900. On the right hand the fingers were all stiff, complete extension being impossible. There was marked atrophy of all the interossei muscles. Trophic changes over the little and ring fingers were evident in the smooth and glossy skin, absence of hair, and furrowed nails. There were anæsthesia, analgesia, and thermic anæsthesia along the ulnar side of the hand, on both sides of the little finger, and on the ulnar side of the ring finger. None of the motor-nerve points gave any response to the faradic current. The left hand presented a condition similar to that of the right, only of far milder type. Although electricity and counter-irritation were tried for several months, the condition remained unchanged. The second case was one of tender toes of typhoid fever. There was absence of redness, swelling, and heat, as well as absence of leucocytosis. The condition gradually abated.

Report of a Case of Cholelithiasis with Formation and Rupture of an Abscess of the Abdominal Wall.—John H. Gibbon reports this case. The patient was a woman aged fifty years. Four years before admission to the hospital she had a severe attack of abdominal pain, low down in the right side, radiating to the umbilicus and occasionally to the right shoulder. Since this attack the patient has had many others and has never been entirely free from pain in the lower right side of the abdomen. The patient never vomited, was never jaundiced, never collapsed from pain, and as far as she knows never passed any gall stones. The conclusion was drawn that there existed an abscess of the abdominal wall. An operation was decided upon. The incision disclosed an abscess dissecting in several directions and containing pus mixed with a clear, thick fluid. On dilating one of the pockets a gall stone was withdrawn and following it fifty-one others. The gall bladder had been opened. During the first week there was a considerable discharge of bile. No jaundice developed after closure of the external fistula. The fistula opened again within a few weeks and discharged bile and mucus, but recently closed again and has remained so ever since.

On Perforation and Perforative Peritonitis in Typhoid Fever.—By William Osler.

The Lancet, January 19, 1901.

The Treatment of Dupuytren's Contraction and Other Points in the Surgery of the Hand.—A. H. Tubby advocates the open method of incision and treatment—that is, the removal by dissection of all the affected palmar fascia. The advantages are: (1) All the fascia can be removed and there is no liability of recurrence. (2) Treatment is shortened, for as soon as the wound is healed splints can be given up. (3) No expensive apparatus is necessary, thin narrow malleable iron splints being all that are required. Certain disadvantages have been urged against the open method. First, it involves a prolonged dissection, but to a skilled operator this in itself is not a matter of great moment; and, secondly, while removal of the indurated fascia in the palm is easy by dissection, it is not possible to dissect it out off the sides of the fingers except in strictly localized bands; and, thirdly, if for any reason the hand should go septic after the operation, the results are disastrous. Concerning the prognosis of tendon division and suture in the hand, the author notes three conditions affecting the result in any given case: (1) The index of tension at which the muscle and tendon are set—*i.e.*, their powers of retraction; (2) the limitation of retraction of the tendon by bands of fibrous tissue binding it in its grooves; and (3) the character of the structures at the spot where division of the tendon occurs—*e.g.*, if division is made where the tendon is surrounded by vascular areolar tissue, plentiful formation of fibrous tissue takes place, and the tendon unites despite considerable retraction of the divided ends. It, therefore, becomes necessary to remember the foregoing three points in forming a prognosis as to the results of tendon division. If the extensor tendons of the fingers are severed, better results can be expected than in the case of the flexors, owing to the closer attachment of the former to the sheaths, to the integument, and to one another. But the retraction is greater when division occurs above the wrist than below it. The extensors of the thumb frequently suffer in wounds of the hand. If they

are divided at the back of the wrist they retract only about 1 cm., as they are more or less bound down by periosteum and good union occurs, but if the division takes place over the metacarpal bone the central end will retract three or four times as much, as the tendons play freely in the sheath, and the latter is very loosely attached to surrounding structures, so that good union is rare. When the wound is at the metacarpal phalangeal articulation of the thumb the prognosis as to healing is good, for the tendons are bound down to the capsule of the joint and cannot retract even though the joint has been opened. The flexor tendons, if divided at the wrist joint, retract very considerably, but the superficial ones less so than the deep, for the former lie in tubes of fasciæ; yet better union occurs here than in the palm of the hand, because the neighboring structures are more vascular and a good uniting bond of tissue is thrown out. A most important point is to keep the wrist fully flexed for at least four weeks after the accident and then gradually to bring the hand into the straight position, taking at least a month to do so. In any operation on the flexor tendons of the hand and fingers the wrist is the seat of election, as it is more likely that new tendon formation will follow, and the exact length of this can be graduated by carefully controlling the position of the hand on the forearm. A recognition of these points is of importance in the treatment of contracted hand for spastic paralysis.

Pneumococcic Arthritis.—E. J. Cave details a round of cases of arthritis seen in connection with pneumonia. He says that the symptoms may vary in severity from pain and slight swelling of a single joint to inflammatory œdema of a joint, or, indeed, of a whole limb with abnormal motility from destruction of the ligaments and with grating of the bared surfaces of the bones. Fever is generally high. The exact nature of the joint affection can be determined only by its association with pneumonia, or other pneumonic infection, and by bacteriological examination of the joint contents. Prognosis is grave both with reference to life and to utility of the joint; to life because of the extreme frequency of infection by the pathogenic organism and its characteristic localizations in the endocardium, meninges, and other tissues (pleura, pericardium, eudocardium, peritoneum, etc.). Treatment calls for hot-air baths, hydrotherapy, massage, douches, etc., and in case of suppuration in the joint, which occurs in the majority of cases, opening of the joint, flushing, fixation, and drainage. Even in cases of serous effusion the author questions whether the result would not be more favorable if an arthrotomy for the removal of morbid products was done. In addition a possible source of generalized infection would be removed. Salicylates are of no avail.

The Relation of the Bowel Lesion of Typhoid Fever to the General Symptoms of the Disease.—T. J. Maclagan says that the action of the typhoid bacillus is a dual one: (1) There is the specific local action of the parasite on the intestinal glands, and (2) the general action on the blood and tissues. The bowel lesion does not cause the fever nor does the fever cause the bowel lesion. Both are conjoint results of the double action of the bacillus. The vast overgrowth of the bacilli in the tissues causes the fever and general disturbance. Neither action would be disastrous in itself or be followed by serious consequences but for the fact that the trouble in the intestinal glands ends in sloughing or suppuration, and many of the features of the later stages of typhoid are due to various organisms (other than the typhoid bacillus) which come into play during these processes of sloughing and suppuration. It is the absorption of these latter germs into the system and their reproduction there that cause the alarming symptoms of so many cases and make typhoid such a dangerous disease.

A Case of Siriasis.—A. E. Griffin details a case of what he calls siriasis, a condition (described under many different names) of intense pyrexia developed by prolonged exposure to a heated atmosphere and which is not to be confounded with that of simple "heat exhaustion." The disease is supposed to be of microbic origin, and it is stated that the special germ has been isolated. It is added that stokers on steam vessels never suffer from the malady and that the latter seems confined to the coast of the Red Sea. A study of the symptoms given does not, in the abstractor's opinion, differentiate the condition from one of severe sunstroke as seen in the northern cities of the United States. Under the heading of treatment reliance seems to be placed on ice-packs together with stimulation by digitalis.

Observations on Wind Exposure and Phthisis.—William Gordon has made a special study of the phthisis death rate in Devonshire. He refers to Haviland's work on the geographical distribution of disease, published in 1868, which included the relation of wind to phthisis mortality. This writer expressed the view that exposure to prevailing winds produces increase of phthisis mortality. In looking over the apparent effects of the various winds, Gordon states that if the north wind were injurious we could not account for the low mortality of the whole north coast; so with the northwest wind. If the northeast wind exercised a very injurious effect it would almost reverse the actual distribution of the death rate. The east wind has access to a great part of the low mortality area, although in this study the three areas of lowest mortality are exempt from it. The southeast wind has fair access to all the areas of low mortality. The south wind has access to all the areas of low mortality, perhaps excepting one. The west and southwest winds only are left. The writer adds that, on the whole, it may be said to be probable that in Devon exposure to west and southwest winds increases mortality from phthisis. It is also interesting to note how the population has avoided these winds. The villages of to-day and the hut circles of primitive ages alike are placed where west and southwest gales can least easily reach them. In the parishes exposed to west and southwest winds the phthisis death rate is nearly three times as great as in the sheltered parishes, while the death rate in the imperfectly sheltered parishes is nearly the mean of those in the sheltered and the exposed. In the district of St. Thomas the phthisis mortality is actually higher on the pervious than on the impervious areas. The presence of wind exposure overshadows any possible influence of soil. In other districts the influence of soil is by no means obvious. But whatever influence seems exerted by soil, it is undoubtedly subordinate to the influence of wind exposure. In these various districts, therefore, the paramount influence which determines a higher or lower rate of phthisis mortality is the degree of exposure to or shelter from the west and southwest winds. This article contains a number of interesting tables.

Jaundice in Typhoid Fever.—George Ogilvie declares that jaundice is generally considered a rare and grave complication of typhoid fever, but the writer believes that its rarity and fatality have been overestimated. His observations show that in some cases of true typhoid fever jaundice may run a course "totally different from what is usually observed," and that this fact alone is not sufficient to construct a new clinical species. It seems almost certain that the etiology is not of a catarrhal nature. The coloration of the stools, the tenderness of the right hypochondrium on pressure which has been observed in one case reported by the writer, and the nausea following from pressure over the region of the gall bladder, all point in a different direction. There are certainly other changes of the liver besides abscess and gall stone which, although rarely, may lead to jaundice in typhoid fever; but whether they can all be regarded as toxic may be open to doubt. But clinical and pathological evidence alike seem to prove that catarrhal jaundice in typhoid fever, so far from being the rule, is an exceedingly rare occurrence. In cases like the two which the author reports in this article "some direct action of the specific micro-organisms on the liver or bile channels" (Da Costa) seems to be the most probable cause of the jaundice, while perhaps the description given by Mathieu—"benign hepatic typhoid"—describes best the clinical aspect of these and similar cases.

Influenza and the Nervous System.—James Carslaw reports several cases, emphasizing several points in conclusion. The illness occurred in otherwise healthy subjects, and at a time when influenza was present in the neighborhood. Some of the cases had catarrhal symptoms considered to be of the nature of influenza. In all, severe headache was prominent, and grave cerebral symptoms developed with alarming rapidity, and, with no apparent cause, in the ears or elsewhere. They were all characterized by very restless delirium, with in the main little or no paresis of limb or ocular muscle to indicate any important localization. Most likely the meningitis was more vertical than basal, though in the only case that was examined post mortem the purulent exudation was found very prominent both at the base and on the convexity, and in this case there had been prominent clinical facts in regard to the pupils, ptosis, and strabismus, indicating that the base of the brain was involved. The writer then reports a case of marked post-influenzal multiple neuritis.

A Note on the Value of Inoculation against Enteric Fever.—Henry Cayley believes that the statistics of the work done in South Africa offer very strong evidence in favor of the protective power of the antityphoid inoculation when this is very carefully performed, and that there is probably necessity for two inoculations at a suitable interval. During the period of five months that the hospital was stationed at Kroonstadt there were ninety-two admissions for enteric fever and eleven deaths. Of these ninety-two patients, fifteen said they had been inoculated, a few were doubtful, and about seventy had not been inoculated. Of the eleven who died, one had been inoculated once, the others had not been inoculated. From these figures probably no conclusions or even reliable inferences can be drawn, but it seems positive from the cases observed that the attacks of enteric fever were, as a rule, much milder in the inoculated than in the non-inoculated, and the duration of the disease was much less.

The Toleration of Arsenic.—By Robert W. MacKenna.

French Journals.

Curability of Uterine Cancer; Necessity of an Early and Correct Diagnosis; Prophylaxis.—Pichevin, after briefly reviewing the history of this subject, states that the cure of malignant tumors by surgical intervention is a problem which has for long years presented itself. Early operation is one of the secrets of lasting cure. In Thorn's statistics, out of sixty-two vaginal extirpations, this operator has found recurrence twenty-seven times in the first two years; but in these twenty-seven cases the intervention had been only palliative, the surgeon had not gone beyond the limits of the cancerous region. On the contrary, those women in whom the cancer was limited to the uterus were really benefited by hysterectomy. There was no recurrence in fifty per cent. of them after a period of over five years. The chief trouble is that the patients come too late to receive the benefit of surgical intervention. This is because the patients do not suffer during the first period of cancerous infiltration and because certain bloody discharges do not attract their attention. It is not so long ago that it was thought that in uterine cancer the health was undermined, but when this state supervenes the growth has already made great inroads and has passed the uterine zone. Uterine cancer may appear at almost any age, even in young women. A fetid odor is generally noticed in the advanced stages. When the patient presents herself, the physician should assure himself by sight and feeling of the condition of the uterus, and carefully establish his diagnosis.—*Journal de Médecine de Paris*, December 23, 1900.

Mammary Tuberculosis.—Édouard Pluyette reports a case of this kind in a girl aged twenty three years. An erosion at the level of the areola offered the port of entry. As the disease progressed the gland became destroyed, and in its examination revealed a purulent focus with all the histological characteristics of tuberculous pus. The milk ducts, however, which were atrophied, showed only signs of inflammation in their walls. The bacillus was found only under the derma. As to the blood-vessels, they were inflamed and their tunics infiltrated with numerous embryonal cells. The lesion seemed to be at a more advanced stage in the vessels than in the lobules. The writer inclines toward the belief that propagation took place by the blood-vessels, rather than by the milk ducts. The course of the disease was relatively rapid: in a month and a half the breast had tripled its size. The course was not the usual one—slow and insidious. Adenopathy was not noted. The gland was invaded in its entirety, consequently the seat of the disease was not external. The affection was limited to the breast, the other organs being sound. The patient was operated on February 1, 1899, and on examination September 15, 1900, she was in the best of health.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, December 27, 1900.

Acute Tuberculous Peritonitis and Appendicitis in a Tuberculous Subject.—Maurice Patel states that even in tuberculous patients in whom the disease is in its infancy an acute appendicitis may occur: it is dangerous on account of the peritoneal reaction. Operation should be early. Even if the immediate result be good, prognosis should be guarded on account of the possible generalization of the disease. Clinical symptoms do not prove in all cases whether there exists a tuberculous appendicitis or an appendicitis in a tuberculous patient. Only microscopical examination can establish the diagnosis. There is an acute tuberculous peritonitis occurring when the disease itself is in its first stages. As a localization of a general infection it can be accompanied by grave peritoneal symptoms which do not differ from those observed in the course of acute perforating appendicitis. The evolution of lesions as the infection extends from the appendix toward the exterior accounts for the occurrence of appendicular and peritoneal complications which may occur and for the necessity of intervention, which ought in certain cases to be early.—*Lyon Médical*, December 30, 1900.

The Adenoid Constitution.—Ch. Lenhardt believes with Huchard that operation for adenoid vegetations is not practised so often as it should be, due to faulty examination or to fear on the part of the parents. In the child called lymphatic the discovery of a cervical adenitis will signify a chronic infection of the pharynx, which it is necessary to remove by the curette or by the application of antiseptics. If it is necessary after this, the iodide treatment or cod-liver oil may be prescribed, or the child may be taken to the seashore or to a mineral-water resort. Rapid success will follow, and the child will pass through adolescence normally instead of being constantly in need of medical attention.—*La Revue Médicale de Normandie*, December 25, 1900.

Berliner klin. Wochenschrift, Dec. 17 and 31, 1900.

Pressure Irrigation in the Treatment of Acute and Chronic Gonorrhœa.—Under this title R. Kutner describes a method which he has found of service. It consists essentially in the introduction into the urethra for a distance of 4 cm. of a Nélaton catheter and the sudden forcible introduction, from a syringe holding from three to four ounces of the irrigation fluid employed, of a small quantity of the same, and then a cessation of the pressure, relaxation of the compression of the organ about the catheter, and the escape of the fluid from the urethra. This manœuvre is repeated until the entire quantity in the syringe has been used. A special model of syringe is devised and figured. Kutner claims that this is the best method of distending the canal and thoroughly cleansing the diseased surface.

Experimental Contribution to Our Knowledge of Alopecia.—A. Buschke has found that by feeding the acetate of thallium to white mice it is possible to produce alopecia which seems to be a peculiar constitutional effect of the remedy, as it did not follow local application. This remedy has been employed in tuberculosis for the relief of sweating. Examination of bits of the denuded skin and of the internal organs of the mice gave no clew to the mode of action of the remedy.

Observations on the Fermentation and Digestion Test of the Fæces and on the Value of the Test Diet for the Examination of Cases of Intestinal Disease.—By Ad. Schmidt.

Deutsche medicinische Wochenschrift, December 27, 1900.

Heat Stroke.—Max Herford enriches the literature with a description of several previously undescribed complications of the common affection. In the one case acute icterus set in, but disappeared in a few days; in another, which ended fatally, the same condition of jaundice came on suddenly and was accompanied by intestinal hemorrhage. In two other instances protracted ataxia and dysarthria prolonged the convalescence, although the intellect was unimpaired and recovery followed. The author explains these various manifestations on the theory that insolation, like burn traumatism, produces destruction of red blood cells with congestion and localized hemorrhages. This has been experimentally proved for burns, and the autopsy on the author's patient showed the presence of multiple hemorrhages in the stomach, endocardium, and intestinal canal. The assumption, therefore, is that the ataxia and inco-ordination of speech were due to small bleedings into the medulla and resemble the encephalomyelitic foci of the "acute ataxias" following the infectious diseases and certain intoxications.

The Therapy of Croupous Pneumonia.—A. Tagesson-Möller describes a method of treating pneumonia said to be popular in Sweden but not as yet in use elsewhere. It is a form of massage whose first object is to lessen the pleuritic pains by repeated firm friction with the fingers in the most sensitive intercostal spaces. The manipulation must frequently be continued for a considerable length of time,

a half-hour or so, but at the end of this period the patient is said to feel much better. "Lateral concussion" of the thorax facilitates resolution and hastens the crisis; concussion of the heart is of inestimable value, but we are warned that unless performed with the utmost skill it is a hazardous manœuvre. Massage of the abdomen stimulates peristalsis, promotes abdominal circulation, and increases renal activity, while headache is to be relieved by appropriate frictions along the various occipital and cervical nerves. The treatment should be repeated every three or four hours, and is said to produce marvellous results, though no statistics are offered.

The Reaction of the Prostatic Fluid in Chronic Prostatitis and its Effect on the Vitality of the Spermatozoa.—H. Lohnstein, as a result of five hundred and forty-two examinations of material obtained by massage of the seminal vesicles from eighty patients suffering from chronic prostatitis, draws conclusions somewhat at variance with those usually accepted. In the majority of cases the secretion, though subject to variations, was found acid and not alkaline as commonly believed. Pus does not appreciably affect the reaction even when it is present in considerable quantity. The reaction of the prostatic fluid does not perceptibly influence the vitality of the spermatozoa, and the presence of retained testicular secretion seems to increase the activity of the prostate.

Ventral Hernia following Abdominal Section.—By R. B. Eads. The author believes that fifteen per cent. of all patients upon whom laparotomy has been performed, if examined five years or more thereafter, will be found to be suffering from post-operative hernia. He then discusses the anatomical structures making up the abdominal wall. The abdominal incision should be parallel, or nearly parallel, with the direction of the motor nerves and of the most important muscular fibres supplied by these nerves. He next describes the various incisions he has found preferable, giving special attention to one overlying the outer border of the cæcum and leading directly to the appendix. It is slightly curved outward and downward, crossing an imaginary line drawn between the anterior superior iliac spines. The centre of this curve is from an inch to an inch and a half to the inner side of the right superior iliac spine. The skin and superficial fascia are incised for about two inches. This freely exposes the aponeurosis of the external oblique, which is separated by means of the dry dissector, or the handle of a scalpel, in a direction parallel to its fibres, and well retracted. This brings into view the transversely arranged fibres of the internal oblique and transversalis muscles and the twelfth abdominal, iliohypogastric, and possibly the ilio-inguinal nerves, all of which are retracted in order to reach the transversalis fascia, which, together with the peritoneum, is divided transversely. The advantages to be gained by this incision are: (1) It provides easy access to the diseased area. (2) It enables the operator accurately and securely to protect the peritoneal cavity from infection. (3) It lessens the liability of breaking down the inner limiting wall of adhesions. (4) It affords a better opportunity to open the abscess cavity from the outer side. (5) It favors drainage. (6) It has not been followed, in the author's experience, by either appendicular fistula or post-operative hernia.

On Traumatic Keloid of the Median Nerve, with Observations upon the Absorption of Silk Sutures.—By Otto G. T. Kiliani. The patient was a girl aged twenty-one years. The following are the salient features of the case: The median nerve is cut through, falling into glass; of course, the usual loss of power and sensation follows. Secondary nerve-suture with silk is done three or four weeks after the accident, after resection of the small bulbi on the distal and central ends. No complete primary union; six weeks later a good-sized neuro-fibroma is found, which interrupts completely the conduction of the nerve. The tumor is again extirpated; the ends are sutured with catgut; primary union is achieved; immediate restoration of sensation and soon that of power; three months after this operation a small tumor has reoccurred, while the skin shows a keloid of a scar. Final result one year after operation: the tumor has nearly disappeared under symptomatic treatment; the hand and fingers are of good use for practical purposes. She attends to her duties of household servant without difficulty. Certain observations are added on the absorbability in living tissue of silk ligatures.

Laryngectomy under Eucaine Anæsthesia, with Remarks on the Technique of the Operation.—By G. G. Davis. The operation was done on a man aged forty-six years, with carcinoma. Death occurred on the fifth day from streptococcus infection. Concerning the technique of the operation and the use of the anæsthetic named, the author sums up as follows: It is feasible to remove the larynx under eucaine anæsthesia. If the two operations are done simultaneously, and a favorable course is pursued, the result will be brilliant, the patient being "out of bed on the fourth day." It is his belief that preliminary tracheotomy ought to be done. We should not sacrifice safety for brilliancy. The leaving of an œsophageal tube projecting from the wound is probably unnecessary, the patient swallowing on the third day. The wound need not be tamponed, but can be closed from the upper edge of the trachea to the hyoid bone. These patients can make their wishes understood by speaking, in a short time after the complete removal of the larynx. In this case it was found comparatively easy to remove the larynx from below upward, going up one side, then across at the hyoid bone, and down the other.

Double Ureter; Report of a Nephrectomy done upon a Young Child with this Condition.—By J. E. Summers, Jr.

An Intestine Holder, Devised for Facilitating the End-to-End Suture of Intestine.—By E. H. Lee.

Scottish Medical and Surgical Journal, January, 1901.

Case of Hypertrophic Osteopathy of Hands and Foot following Amputation at the Hip Joint for Sarcoma.—J. M. Cotterill reports the case of a man aged nineteen years, suffering from periosteal sarcoma affecting the lower end of the right femur. Amputation was performed a little above the middle of the femur. Twelve months later he returned with a small sarcomatous mass at the lower end of the stump; disarticulation at the hip joint was performed. During convalescence there was a rise of temperature, and there was found evidence of effusion of fluid at the base of both lungs. The hands and foot became enlarged, the condition progressing for two months and then remaining stationary. A radiograph of the hands showed the formation of new bone along the shafts of the metacarpal bones and phalanges. The lung trouble which was due to secondary sarcomatous infiltration steadily increased, and the patient died two years after the first operation.

Douche Massage.—Charles Begg was strongly impressed by this form of treatment as given at Aix-les-Bains, for the purpose of stimulating elimination, and for tonic stimulation of the nervous system. For ten or fifteen minutes the water plays on the patient from two hose, each part of the body receiving attention in turn, while the water of the ordered temperature and force is applied simultaneously with the massage. The supply of water must be copious, it must not be of too marked a character, *i.e.*, it must not be too briny or too gaseous, and it must be a natural thermal water. The patient must be operated on while his muscles are perfectly relaxed. The massage, while thorough, must never be severe enough to cause pain. All cases requiring increased excitation, elimination of toxic products, restoration of impaired or dormant function, or the establishment of heightened condition of nervous and vascular tone, are subjects for the treatment if it be wisely adjusted to each case.

Cleidotomy; an Operation Accessory to Craniotomy or Basilysis.—J. W. Ballantyne gives the following outline of his detailed article. Cleidotomy: Division of the clavicle. Indications: (1) Broad-shouldered fœtus. (*a*) Normal sized head; (*b*) large head; (*c*) deformed head (anencephalus). (2) Contracted pelvis. (*a*) Justo-minor; (*b*) flat rachitic; (*c*) kyphotic. (3) Broad-shouldered fœtus in contracted pelvis, neither excessive. (4) Impacted shoulders in breech case. (5) Danger from eclampsia, threatened uterine rupture, etc., necessitating rapid delivery. In all (or nearly all) its indications, cleidotomy is accessory to craniotomy or basilysis, and is carried out upon the dead infant; but these are not essential restrictions. The author describes its advantages over ordinary embryulcia of the shoulders and evisceration of the thorax. He also describes his operation.

The Treatment of Rheumatic Fever.—Arthur P. Luff finds that this disease is most successfully treated by giving a combination of a salicyl compound with an alkaline

bicarbonate. For an adult gr. xx. of sodium salicylate and gr. xxx. of potassium bicarbonate should be given every two hours until the pain is relieved and the patient is fully under the influence of the salicylate, when the same quantities should be given every four hours till the temperature has fallen to normal. Afterward gr. xv. of the salicylate and gr. xx. of the bicarbonate are to be given every four hours until all the joint symptoms have disappeared, and then three or four times a day until a fortnight has elapsed from the complete disappearance of joint symptoms. During the whole of this course of treatment absolute rest in bed must be enforced. The heart should be carefully examined each day during the administration of the salicylate and the alkali, as they tend to exert a depressing effect on it. The application of salicylate of methyl to a painful and inflamed joint is a recent and good method of relief. The author describes various methods of treatment in detail.

The Epidemiology of Rheumatic Fever.—Arthur Newsholme submits evidence in demonstration of the occasional epidemic prevalence of rheumatic fever. Direct infection from patient to patient is rare, if it occurs. As to the reason why dry years favor epidemic rheumatic fever, it seems most feasible to regard rheumatic fever as essentially a soil disease, due to a saprophytic soil organism, which is "drowned out" in wet years, multiplies rapidly in dry years, and is transferred to the human recipient by unknown means. Possibly dust convection accounts for a large proportion of the cases. In dry years the number of contagious particles is probably increased, and the facility with which they are communicated to the human subject is similarly increased. In the light of our recent acquired knowledge of the methods of infection in malaria, it is not perhaps too far-fetched to surmise that inoculation of the contagium of rheumatic fever may be caused by domestic vermin or that the house fly may convey it to milk or other foods.

The Pathology of Rheumatic Fever.—F. J. Poynton reviews the various theories held as to the causation of this disease. From experimental work the author states that the diplococcus which he has isolated is a cause of rheumatic fever. As yet he is not in a position to state that it is the only cause, but he believes that this organism will eventually prove to be the actual cause of all cases of rheumatic fever which conform to the usual type of the disease. One of the most important sites of infection in rheumatic fever is generally admitted to be the throat; the diplococci are found in the tonsils in rheumatic angina. They are present also in such cardinal lesions as the nodules, the pericardial exudation, the inflated valves and pleura, and produce identical lesions in the rabbit. In rheumatic fever the connective tissues suffer greatly, and the diplococci are found with the least difficulty in these tissues.

The Effects of Rheumatic Fever on the Heart.—By G. A. Gibson.

Rheumatism in Childhood.—By George F. Still.

Russkiĭ Arkhiv Pathologii, etc., November 30, 1900.

The Diagnosis and Pathology of Acute Myelitis.—W. A. Mouratoff holds that the parenchymatous changes in the fibres and cells are not due to an affection of the blood-vessels, but to direct effect of the intoxication. There are three forms of acute myelitis: (1) The acute hemorrhagic, characterized by a brusk onset, (2) the acute interstitial, which may be focal or disseminated, and (3) the parenchymatous diffuse, which has a progressive ascending or descending course. The changes in the spinal cord which complicate Landry's paralysis are not always medullary, but may consist of a true parenchymatous myelitis.

The Influence of Fecal Absorption on the Blood.—By G. Borodulin.

Revue de Médecine, December 10, 1900.

Opotherapy in China and Indo-China.—Jules Regnault says that in these countries the testicular juice of the tiger is used for impotence. Under the supposition that the eyes and the liver are closely connected functionally, mosquito eyes mixed with pig's liver is given for conjunctivitis. Pig's liver is also given for icterus, congestion of the liver, and hepatitis. Goat's liver mixed with various plants is administered for diseases of the eyes or of the liver. Bear's gall is highly esteemed for the same purposes, but is very expensive. Pig's lungs are used for cough, especially in chronic bronchitis. Pig's kidneys are prescribed for renal affections. For gastritis the coats of a young chicken's gizzard are supposed to be curative. Women take pieces of dried placenta to facilitate labor. Human blood is supposed to be strengthening, and at executions the executioner, and even the spectators, eat the blood, the liver, and the bile of the victim to increase their courage.

Pleuro-Typhoid, and Pleurisy due to Eberth's Bacillus.—Paul Remlinger concludes that pleurisy occurring during the course of typhoid fever is nearly always caused by Eberth's bacillus. The pleurisy may be serous, hemorrhagic, or purulent. Pleuro-typhoid as a distinct morbid entity is a serous pleurisy preceding the appearance of benign typhoid. Pleurisy occurring during the course of typhoid is more serious. The prognosis will depend upon the purulence. This form of pleurisy is characterized by its tendency to predominate on the left side, the slowness and subacute character of its development, and its tendency to become sterile by gradual attenuation and the disappearance of Eberth's bacillus. An interesting class of cases of pleurisy due to the typhoid bacillus is found when the pleurisy is the result of secondary infection during the course of some other affection, as tuberculosis. This special point calls for further research.

The Etiology of Vitiligo.—E. Gaucher thus classifies the pigmentary dystrophies of the skin: (1) Symptomatic or trophic, of nervous origin, pigmentary cutaneous alterations from diseases or lesions of the nervous system. (2) Dystrophies of toxic etiology and nervous pathogenesis, including (*a*) hyperchromatosis of toxic origin properly so called, as arsenical melanodermia. (*b*) Achromatosis and dyschroia of toximicrobian origin, such as the leucomelanodermia of syphilis, and the white spots of leprosy. (*c*) True vitiligo of autotoxic origin, in relation with some previous nutritional disturbance.

Gastric Crises and Syringomyelia.—R. Pauly reports a case in which gastric crises characterized the onset of syringomyelia. They were of the nature of the crises in tabes, sudden, without apparent cause, of a violent, tearing character, accompanied by copious and sometimes very acid vomiting, ceasing bruskly after eight or nine days. They reappeared at intervals, and were controlled by opium. The patient thought that iodine also had a good effect.

Reviews and Notices.

A Treatise on Mental Diseases. By Dr. Henry J. Berkley, Clinical Professor of Psychiatry in the Johns Hopkins University. New York: D. Appleton & Co.

This concise, practical work on mental diseases is a revision of the author's lectures delivered at the Johns Hopkins University in 1899. Part I. is devoted to the anatomy and histology of the central nervous system. Were it not that the forty-four pages thus taken up contain an epitome of much of the author's original and excellent work, this might appropriately have been omitted. There was a time when the anatomy and physiology of the nervous system were unknown and forbidding subjects to the average physician. That is now, happily, a thing of the past. Part II. contains a section on the boundary lines between degenerating and non-degenerating types of insanity, and a full, adequate discussion of the pathological alterations of the neuron and the blood-vessels in insanity. The author's appreciation of the frequent occurrence and the far-reaching effect of arteriosclerosis is especially gratifying. In the discussion of the general etiology of insanity we are of the belief that the author lays too much stress upon the deleterious results of alcohol. The commendable features of the writer's remarks on general treatment are brevity, conciseness, and lucidity, and the latter despite many verbal infelicities, such as "hyoscine requires careful watching"; "to avoid the stigma which might remain attached to him forever afterward"; "to resume the broken habit of sleep," etc. The special forms of insanity are next considered. In the portrayal of melancholia we miss reference to its average duration. Taken in its entirety the chapter on mania is quite satisfactory. Under a subheading of states of mental stupor the writer discusses

acute curable dementia. In this connection reference should have been made to dementia præcox. And one of the conspicuous shortcomings of the book is that this matter to which so much study has been given both in this country and in Europe is not considered. The chapter on general paralysis is one of the best in the volume. The writer is the first of the systematic writers to depart from the custom of depicting in exaggerated terms the megalomania and boundless exaltation of the paretic. That the symptomatic clinical features of general paresis have undergone a change has lately been pointed out by Collins, Mendel, and others, and Berkley's description seems to be in harmony with the statement of these writers. The intoxication insanities receive adequate consideration for the first time in American psychiatric literature. The chapters devoted to the insanities of the psychical degenerate suffer by comparison with those in more than one modern French and German treatise. The chapter on neurasthenia does not call for special mention save to say that it does not fit the treatise. The volume closes with an excellent chapter on the psychoses of childhood. The reviewer, and no doubt many readers who are also puzzled, would be thankful for an interpretation of the author's prefatory note in which it is said that the volume was written because of "the absence from English medical literature of a comprehensive, practical work on mental diseases." We are fearful of giving the impression of forced credulousness by hinting that Kellogg's excellent work, a credit to clinical psychiatry, Macpherson's masterly book, Clouston's comprehensive and readily assimilated small treatise, not to mention the many others constituting a veritable embarrassment of riches, were overlooked.

Practical Gynæcology: A Comprehensive Text-Book for Students and Physicians. By E. E. Montgomery, M.D. Containing eight hundred and nineteen pages and five hundred and twenty-seven illustrations. Philadelphia: P. Blakiston's Son & Co.

The first thought, on seeing the announcement of a new work on gynæcology, is one of sadness, for the medical world is already oppressed with the rapidly accumulating weight of ponderous tomes on this subject. A new text-book on gynæcology, to be acceptable at the present day, must have an excellent reason for existence. The author of the present work is evidently of like mind, yet having a reason for the faith that is in him, he boldly declares, "I will offer no apology for presenting an additional text-book upon gynæcology." And he need not do so, for even the most casual reader does not have to look far through this excellent text-book before he discovers that every page is permeated with the spirit of the true teacher. There is a refreshing absence of that verbosity which mars so many works of this class; the searcher after practical information, on any topic in the domain of gynæcology, is not compelled to wade through tedious descriptions enveloped in a haze of details and theories, but is quickly rewarded by finding what he wants crystallized from a rich experience into a few crisp sentences. To make clearness doubly clear, high-class illustrations are freely introduced. Nearly all of them have been drawn and engraved specially for this work, for the most part from original sources. The arrangement of the book is decidedly original, and is sure to commend itself to the student. Instead of being divided into chapters, it is made up of sections, each general subject being considered with reference to its influence upon the entire genital tract. The plan and scope may be best understood by an enumeration of the principal headings, viz.: (1) Diagnosis; (2) therapeutics, medical and local; (3) anatomy; (4) physiology; (5) malformations, including such acquired ones as injuries to the perineum, vagina, and cervix; (6) inflammation; (7) deviations of the pelvic organs; (8) genito-urinary hemorrhage and ectopic gestation, and (9) genital tumors. The book is bound to become the valued friend and companion of the general practitioner as well as the student.

Notes on Surgery for Nurses. By Joseph Bell, M.D., F.R.C.S. Edin., Consulting Surgeon to the Royal Infirmary and to the Royal Edinburgh Hospital for Sick Children. Fifth Edition, thoroughly Revised. Edinburgh: Oliver & Boyd, Tweeddale Court. London; Simpkin, Marshall Hamilton, Kent & Co., Ltd. 1899, pp. 194.

A thoroughly practical book for the guidance of nurses, such as this is, naturally has proved popular, and the fifth edition will probably be as favorably received as its predecessors. The articles treated in this volume include inflammation, suppuration, ulceration, gangrene, pyæmia and septicæmia, the healing of wounds, burns and scalds, fractures and dislocations, tumors, special operations, the surgical nursing of children, and general advice to nurses. The author evidently has a keen insight into the difficulties of nursing, and attempts very successfully to clear up all obscurities and the troubles which are commonly met in hospital and private practice.

Pathologie und Therapie der Erkrankungen des peripherischen Nervensystems. Von Dr. med. Franz Windscheid.

This book is merely a compendium of the subject upon the diseases of the peripheral nerves. It meets all the requirements which could be justly expected of books of this kind. Without entering into the minute details of the anatomy of the nervous system, its physiology and pathology, the author touches upon these subjects so far as a clear and thorough understanding of the diseases above alluded to may require. The symptomatology, differential diagnosis, and therapy are as clearly and precisely mentioned as the limits of the work would allow. In the first part the author treats upon the diseases of the peripheral sensory nerves; in the second part, upon the motor nerves, paralysis, spasms, and inflammatory conditions—neuritis. The illustrations are very simple and convey a clearer understanding of the text. This book is therefore strongly to be recommended as an introduction to the study of the diseases of the peripheral nervous system.

An American Text-Book of Physiology. By Henry P. Bowditch, M.D., John G. Curtis, M.D., Henry H. Donaldson, Ph.D., W. H. Howell, Ph.D., M.D., Frederic S. Lee, Ph.D., Warren P. Lombard, M.D., Graham Lusk, Ph.D., F.R.S. (Edin.), W. T. Porter, M.D., Edward T. Reichert, M.D., Henry Sewall, Ph.D., M.D. Edited by William H. Howell, Ph.D., M.D., Professor of Physiology in the Johns Hopkins University, Baltimore, Md. Second edition, revised. Vol. I., pp. 598. Philadelphia: W. B. Saunders & Company. 1900.

In the present edition of this very popular text-book the authors have concluded not only to rearrange the subject matter but also to issue the work in two volumes. The introduction is by the editor, as are the articles on the blood, the lymph, on secretion, on the chemistry of digestion and nutrition, and on the movements of the alimentary canal, bladder, and ureter. Dr. John G. Curtis contributes the article dealing with the mechanics of the circulation of the blood and of the movement of the lymph. Dr. W. T. Porter writes on the innervation of the heart and blood-vessels and on the nutrition of the heart. Respiration and animal heat by Dr. Edward T. Reichert, and the chemistry of the animal body by Prof. Graham Lusk, complete the first volume.

A Practical Treatise on Fractures and Dislocations. By Lewis A. Stimson, M.D., LL.D., Professor of Surgery in Cornell University; Surgeon to New York and Hudson Street Hospitals, etc. Third edition, revised and enlarged. With three hundred and thirty-six illustrations and thirty-two plates. New York and Philadelphia: Lea Brothers & Co. 1900.

The appearance of a third edition of this work one year after its second is sufficient guarantee of its popularity. There are no marked changes from last year's volume, though there have been some condensation and some additional material, and a considerable number of new illustrations have been added. The Hudson Street Hospital in this city furnishes an unsurpassed field for the study of fractures and dislocations, and of this the author has made good use. It is hardly necessary to recommend a book which is so well known.

A Reference Handbook of the Medical Sciences, Embracing the Entire Range of Scientific and Practical Medicine and Allied Science, by Various Writers. A New Edition. Completely Revised and Rewritten. Edited by Albert H. Buck, M.D., New York City. Vol. I. New York: William Wood & Company. 1900.

It was fifteen years ago that the first volume of the first edition of this wonderfully useful work of reference was published, and a comparison of the two books shows in a striking way the great strides that medicine has made in this last decade and a half of the nineteenth century. In the old edition the last article treated was "Cataract"; in this edition the titles have advanced only to "Bladon Springs," and such large subjects as "blood," "brain," and "carcinoma" being pushed over into the second volume. Many of the articles have been greatly expanded, "actinomycosis," for example, filling four pages instead of one, and "air" eleven instead of six. But we also find many new subjects treated of here; for example, "acromegaly" in eleven pages, "adiposis dolorosa" in six, "adrenal glands" in four, "pathogenic amœbæ" in five, "history of anatomy" in twenty, "appendicitis" in six, "pathogenic bacteria" in forty-five, etc. Most of the important articles

have been rewritten, sometimes by the original authors, sometimes by new ones. The use of full-page plates is on a much more generous scale than in the first edition, this volume containing twelve in place of the four which were admitted to the first volume of the other edition. We find many cross-references in this volume—a useful feature which the first edition lacked. Indeed, all the changes which have been made are distinctly in the way of improvement, and cannot but increase materially the value to the practitioner of this almost indispensable work.

THE AMERICAN ILLUSTRATED MEDICAL DICTIONARY. A New and Complete Dictionary of the Terms Used in Medicine, Surgery, Dentistry, Pharmacy, Chemistry, and the Kindred Branches, with their Pronunciation, Derivation, and Definition, Including Much Collateral Information of an Encyclopædic Character. Together with New and Elaborate Tables of Arteries, Muscles, Nerves, Veins, etc., of Bacilli, Bacteria, Diplococci, Micrococci, Streptococci, Ptomains, and Leukomains, Weight and Measures; Emponymic Tables of Diseases; Operations, Signs and Symptoms, Stains, Tests, Methods of Treatment, etc. By W. A. NEWMAN DORLAND, A.M., M.D., Assistant Obstetrician to the University of Pennsylvania Hospital; Editor of the American Pocket Medical Dictionary; Fellow of the American Academy of Medicine. Philadelphia and London: W. B. Saunders & Company. 1900.

THIS is the latest of the medical dictionaries to make an appeal for public favor, and it ought not to make it in vain. It is well arranged, the type is good, the definitions are clear and correct, and the tables are useful. The book is bound in flexible covers, and is not large enough to be inconvenient to handle. The plates, of which several are colored, are very well done.

(From our Special Correspondent.)

NEW YEAR'S HONORS FOR DOCTORS—PERIPHERAL NEURITIS FROM ARSENICATED BEER—CIRCULATORY PHENOMENA AS SEQUELÆ OF THE PREGNANT UTERUS—BRADSHAW LECTURE ON HERNIA.

LONDON, January 4, 1901.

WE have had rather a dull week as regards medical matters, which have paled in interest before a fresh outburst of hero worship of which, no doubt, you have been kept informed by cable.

The weather, too, has been depressing—a wet Christmas followed up by dull rainy days with a temperature considerably above the average for the time of year. To-day London is plunged in a dense fog and all the inconvenience which results therefrom.

The list of honors conferred by the Queen on the occasion of the New Year is rather disappointing, considering that the date also marks the commencement of the new century. The profession hardly gets its share this time. The president of the College of Physicians (Dr. Church) receives the customary baronetcy. The same honor is given to Dr. Thomas Barlow, one of the court physicians. Both these gentlemen are highly esteemed by their brethren. Sir William Turner gets a K.C.B., Dr. Frank Simon, P. M. O. of the Straits Settlement, a C.M.G.; Dr. Adcock, physician to the Shah of Persia, a knighthood. The Kaiser-I.-Hind gold medal for public services in India has been conferred on Dr. Arthur Neve, of the Medical Mission Hospital, Kashmir. Colonel J. S. Wilkins, I.M.S., receives the same distinction. Major John Crimmin, V.C., I.M.S., is given a C.I.E. Among non-medical recipients I may mention as of interest to the profession that a G.C.B. is conferred on Lord Justice Romer, the president of the commission on the war hospitals; and Mr. E. H. Busk, chairman of convocation of the London University, is knighted.

The epidemic of peripheral neuritis from arsenicated beer was fully discussed at the Liverpool Medical Institution, when several of those who had been occupied with numerous cases and taken a part in elucidating the matter related their experience. We are also to have a discussion on the subject here, and no doubt many papers will be published in the next few weeks. The discussions I may be able to consider in a future letter.

A paper entitled "Circulatory Phenomena as Sequelæ of the Pregnant Uterus" was read at the Gynæcological Society on the 13th ult. by Dr. H. Hodgson, vice-president. He began by remarking that the common theories of the cause of labor at full term did not attach sufficient importance to the blood supply. Thus, overdistention, sometimes advanced, does not explain why the uterus ceases to grow and would seem more likely to paralyze muscular contraction. Then fatty degeneration of the decidua, leading to separation of the placenta and making the ovum a foreign body, is also unsatisfactory, and Dr. Hodgson asks why should the degeneration occur at a particular period, and why should the ovum act as a foreign body while still receiving blood through the placenta? Again, if, as some suppose, the onset of labor at the tenth month is due to congestion at a menstrual epoch, why not at the eleventh or any other monthly period? Further, if the fœtus at full term has the power of exciting uterine contractions, we must also admit that it is able sometimes to induce labor at the seventh or eighth month. Then, why, asks Dr. Hodgson, should it not sometimes lack that power until, say, twelve months? Once more, if ovarian irritation is the law of parturition, Dr. Hodgson asks, why are the ovaries excited to exactly this point at nine months—why not at twelve? And what about labor when the ovaries have been removed months before delivery? Having thus set puzzling questions to the advocates of these several theories, Dr. Hodgson proceeded to develop his own. He attributes the setting in of labor to the failure of nature to maintain the balance between the rate of growth of the pregnant uterus and its contents. This, of course, largely depends on variations in the blood supply, and the circulatory phenomena come therefore to have great significance. Having discussed them at some length, Dr. Hodgson summarized his view in a style not often heard at a medical society, as follows.

"From the moment conception takes place a race commences between the uterus and the ovum. The uterus becomes rapidly active, its walls charged with blood; with wonderful celerity it lays down muscular tissue, and even its mucous membrane swells with pride at having captured a live ovum. The ovum, at first an insignificant being in the uterine cavity, gradually develops and threatens the uterine walls, recognizing which the uterus hastens on with both its development and expansion until the end of six months, when finding that its competitor in the race having won, the inside of the circle is pressing so forcibly upon its food supply that it gives up the contest and allows the fœtus to expand its cavity at will, with the ultimate result that the fœtus, given a free hand, continues ruthlessly to press upon the uterine walls to such an extent that it cuts off its own blood supply to the placenta, which therefore dies. The fœtus, beholding with fear what it has done, shrinks, the uterus, thereby released from some of its strain, seizes the opportunity, opens its mouth, belches forth its intruder, and collapses."

Now, if you do not understand the mystery of the cause of labor, you can follow the doctor's example by asking questions such as he has put to other theorists.

The Bradshaw lecture at the Royal College of Surgeons was delivered on the 12th ult. by Mr. Langton. It is now eighteen years since the first lecture of this foundation was delivered by the late Sir James Paget, whose death, since the last lecture of the series by Mr. Howse, was gracefully alluded to by Mr. Langton. He spoke of Paget's career, whether considered in its professional and scientific aspects or in his deeply religious life, his untiring energy, ceaseless work, and never-failing courtesy, as affording a noble example and a pattern for all time. Mr. Langton then passed on to the subject he had chosen, which was the association of inguinal hernia with the descent of the testis. He discussed at length the several varieties of congenital hernia. Of these the one called variously interstitial, intermuscular, ascending, intraparietal, interparietal, and properitoneal may be mentioned. The last name he thought the worst, as it gave no clew to the position of the hernia in the abdominal walls. He preferred the term interstitial, as, although it did not give much information, it is not incorrect as to structural relations; for this hernia is primarily situated within the muscular walls, usually in the patent vaginal process, within which lies an ill-developed testis. It is not very frequent, for out of a total number of fifty thousand cases of hernia only forty-two of this form were recorded, a proportion of one to eleven hundred. Analogous forms of hernia in females are not so rare, the statistics showing them to be twice as frequent as in males. Most of them occurred in mothers of large families, and are probably due to distention of the abdomen during pregnancy.

The treatment of interstitial hernia in males, Mr. Langton said, is neither scientific nor satisfactory. The pressure of a truss is mainly directed to covering the hernia and seldom effects complete retention. The deviated testes accommodate themselves under the truss if it is perfectly adjusted. Operative measures are often very difficult; the complete approximation of the separated parts may be impracticable. The size of the hernia may be so great that the abdominal cavity cannot receive it, and the question of enterectomy may arise to allow complete reduction of the extruded mass.

Society Reports.

THE PRACTITIONERS' SOCIETY.

One Hundred and Sixtieth Regular Meeting, Held on Friday, January 4, 1901.

ANDREW H. SMITH, M.D., PRESIDENT PRO TEM.

A Case of Post-Typhoid Neuritis.—This was presented by DR. V. P. GIBNEY. Lizzie D——, fourteen years of age, was admitted to the hospital on July 13, 1899. The history, obtained from her mother and Dr. Leyendecker, in charge of the case, was that she was perfectly well up to September, 1898. She developed what was first regarded as malarial fever, and then, a little later, typhoid. No blood examination was made, but the fever was of a low type; there were many spots over the abdomen, and there was suppression of urine four or five weeks after the beginning of her illness. She was unconscious and delirious at times, and had several bedsores. Living on the top floor of a tenement and her parents being very poor, no accurate records were kept, but Dr. Leyendecker remembered all these points and had no hesitancy in making a diagnosis of typhoid. Four weeks after the beginning of her illness she developed a double neuritis, involving both lower extremities. Deformity followed rapidly in her attempts to get the limb into the most comfortable position. She had hyperæsthesia and pain, requiring a liberal use of anodynes. About Christmas, 1898, when the fever had abated, the limbs were pulled down under chloroform, and a plaster-of-Paris dressing was applied. This was soon removed, and the deformity remained. She was quite helpless when brought to the hospital, and presented a picture of extreme deformity and disability. Both thighs were held fixed at an angle of 120°; while the left one was in extreme adduction, the right was in moderate abduction. On the left side the trochanter major was above Nélaton's line; the right leg was flexed at an angle of 150°, and the left at an angle of 140°. The feet were in extension, and the entire limb on each side was very sensitive. The sacrum was pretty well covered with cicatrices. It was difficult to determine whether any power existed in the limbs or not; the anterior tibials certainly seemed paralyzed. There was upward dislocation of the left hip. There was a small range of motion at the knees, passively. She was kept in bed until the 22d of August before any attempt was made at correction of the deformity. Then, under gas and ether, the Achilles tendons were divided, and the thighs and legs extended very nearly to normal. Dr. Whitman was in charge of the speaker's service during the summer and no attempt was made to reduce the dislocation of the hip at this time. The plaster, which extended from the free ribs to the ball of the foot, was not removed until October 16th, during which interval she had been fairly comfortable. The limbs were found straight, but there seemed to be no voluntary power in either limb. Massage and slight passive movements were begun. On October 24th Dr. Gibney succeeded in reducing the dislocation. The hip was abducted a good deal and put up in plaster of Paris. On November 23d the plaster was removed and traction made by weight and pulley for a short time. The next note is on January 4, 1900, when her condition was good. There was a good deal of lumbar lordosis, showing that the deformity at the hips had recurred to a moderate extent. During the winter and spring power slowly returned to her limbs. Active and passive movements were continued, and on the 31st of May it was noted that she was walking about the ward without the use of a cane. It was thought best, however, to protect the joints by apparatus, but on June 14th she fell and injured the left hip again. She spent the summer in the country, getting about very well. In the fall it was noted that there was some deformity at the hips, and under an anæsthetic this was reduced. On October 18, 1900, she was able to walk much better, but still a little deformity existed, more on the right side, so on the 23d the hip was stretched again and traction put on. On December 4th it was necessary to put the hips in position again, since which time she had remained perfectly straight. There was some arthritis of the right knee, hence the delay in getting about. All the symptoms of neuritis seemed to have disappeared. The action of the ankles was good, that of the knees and hips was improving, and the limbs were equal in length. The femoral head had remained in the acetabulum. The history of this case, Dr. Gibney stated, was a long one, yet he had attempted to make it as brief as possible. The aim had been to secure a perfect result; and in view of the ease with which recurring deformity could be overcome and passive movement so soon resumed, the prognosis was good.

A Case of Typhoid Hip.—This was likewise presented by Dr. Gibney. Mr. F. G. S——, thirty-six years of age, was seen at the request of and in consultation with Dr. John Woodman on November 8, 1899. The patient had previously been seen by one or two other surgeons, who also suggested that the speaker see the patient and make some effort at the reduction of his deformity. The history furnished by Dr. Woodman was this: Mr. S—— had been feeling poorly for several weeks during the summer of 1899, but did not feel really ill until August 5th, and on August 10th his temperature was 103°. A diagnosis of typhoid was made and he was put to bed. From this time on he had a rather high temperature, and was treated with tub baths, which seemed to have a very favorable effect on the pulse and temperature. On August 26th, at 5:45 P.M., just before he was to have his bath, he had an intestinal hemorrhage. The bath was not given, but instead a hypodermic of ergot and morphine was administered, and a few days later the bloody stools ceased. On the 30th of September at 10:30 P.M. he complained for the first time of pain in the shoulder. This pain increased in severity, involving both the shoulder and the arm until October 3d, when it gradually diminished in severity. On the same date, September 30th, at the same hour, he was seized with pain in the left hip in the region of the groin and acetabulum. Local swelling soon followed, with flexion deformity and a great deal of tenderness. Shortly after this his temperature came down to within a degree of the normal, but the pulse continued high, 115 to 125, most of the time. On the date of the speaker's first examination, about three months from the beginning of the patient's typhoid and two months from the beginning of his hip symptoms, the left hip was found flexed at an angle of 90°, the knee at an acute angle, and the foot extended. It was difficult to make any reduction of the deformity on account of the great pain and deep resistance. The infiltration about the hip was not very pronounced, yet it was present. The shoulder at this time was only slightly ankylosed and was improving. On November 10th, under gas, and with the assistance of several gentlemen, Dr. Gibney succeeded in pulling the limb into very good position, getting the hip down to 170°, the knee to about 170°, and the foot up to a right angle. Much force was necessary to accomplish this, and the breaking down of adhesions could be heard at all the joints. He put on plaster of Paris from the foot to the free ribs. Under a little morphine and other narcotics he succeeded in keeping the plaster on until December 6th, and with the exception of a small pressure sore over the middle third of the crest of the tibia, there was no ex-

coriation on the removal of the plaster. He would mention that there was a bedsore over the sacrum at the time of operation, which was not covered by the plaster. He found the limb quite straight and parallel with its fellow. The hip could not be brought down to quite 180°, but the knee could. He did not find it necessary to put on traction, as there was no spasm, and the plaster was not renewed. Under massage and active and passive movement the patient improved so that by December 31st he was able to stand with a little assistance. The bedsore had entirely healed. There was very little swelling about the foot or ankle. He could flex his knee over 10° or 15°, and had a little motion at the hip and ankle. At this time he was sitting up an hour a day. Nearly one month later, January 22d, he went downstairs and resumed his duties in the store. In his efforts to sit erect and to get about he lost some of the good result at the hip, and on the 28th of February it could not be extended beyond 165°. The speaker's last note was on May 14, 1900, when the patient's angle of greatest extension was about 150°, and angle of flexion very little better than this. He was able, however, to sit down with very little effort and to get his back well against the chair. He had a distinct limp, but got about easily with a cane. The knee action, both in flexion and extension, was very good, the limbs were equal in length, the left thigh was one inch smaller than the right, the knees were the same size, and the left calf was three-fourths of an inch smaller than the right. He rarely had any pain. He had been under massage, and had spent some time in Atlantic City, Lakewood, and Sullivan County. He was advised to have his hip moved under an anæsthetic, as his general health was excellent. This advice was not urged upon him, and no further operation had been attempted. Dr. Gibney added that the first case of typhoid hip, which he had seen on the 21st of April, 1888, in consultation with Dr. William M. Polk, was the following: Miss H——, eighteen years of age, was in good health and free from lameness or deformity until the evening of the 5th of April, when she had a chill. This was followed by fever, etc., and she was treated for typho-malarial fever. She had purpuric spots on the dorsum of both hands, had had temporary, well-pronounced paralysis of the extensors of the right wrist, and had complained almost from the first day of pain in the region of the anterior crural distribution, and occasionally in some of the branches of the sciatic. Once or twice Dr. Polk had tried traction, but this seemed to aggravate the pain. In proportion as her constitutional symptoms subsided, in that proportion her nervous symptoms were seemingly aggravated. Pressure over the hip region had at times given relief; at other times there had been much cutaneous hyperæsthesia. She had not made any attempt to stand since she was taken sick. Within the past week it had been very difficult to move her limb in bed and any jarring of the bed or floor caused her to cry aloud. She had become very timorous and manifestly hysterical. She had not lost flesh. She had had no spinal tenderness, but had some tenderness and pain over the left ovarian region; none now. At the time of his first examination, the limb lay parallel with its fellow on a pillow and wrapped in flannel. With much care a little rotation could be made. There was no atrophy of the limb. It was impossible to test the functions of the hip, as the patient was so frightened. Weight and pulley, sixteen pounds, were applied and gave her much relief. After a few days a long splint was applied. On May 16th she was easy and comfortable, resting well at night, and all fever had left her. She was walking about the floor on the splint and axillary crutches. There were no reflex spasm and no joint tenderness, but a dull aching pain was felt in the region of the anterior crural. On June 20th the splint was removed. She had steadily improved and gained in strength. The joint functions were about three-fourths normal. In July she went to Europe, and while abroad was treated at various places with baths, cold douches, massage, etc. On her return the following October she was very strong and muscular. There was no limp, the limbs were equal in length, and there was no atrophy. Flexion and extension were perfect, but the limb was adducted a little. The speaker's last note was on December 13, 1889. At that time she had a slight limp. External rotation of the left thigh was limited to about one-fourth normal, and abduction to about one-half that of the right side. The limbs were equal in length, and there was no atrophy of the thighs or calves.

In reply to a question as to what the actual changes in the joint were in those cases in which a dislocation occurred, Dr. Gibney said that with a severe neuritis the patient would naturally seek the most comfortable position, and if the muscular spasm was pronounced and the tissues about the joint were much relaxed, a spontaneous dislocation might result. In those cases of ancient dislocation of the hip in which the acetabulum did not contain much adventitious tissue, the head of the femur could be replaced and held there by plaster, and the weight of the body in walking gradually disposed of the adventitious tissue. Even when there was a very shallow acetabulum Lorenz advised that the head be replaced and kept there by plaster, and in time the head made an acetabulum for itself. In congenital dislocation of the hip this procedure had given very good results.

Two Cases of Amputation at the Hip for Tuberculous Hip-Joint Disease.—These were presented by Dr. Charles McBurney. The first patient was a boy thirteen years old, whose hip-joint trouble was first noticed when he was three years of age. According to the history, he had received excellent treatment, and at times he was to a large extent relieved of his symptoms. The disease recurred, however, from time to time, and when Dr. McBurney first saw him, two years ago, he was much emaciated and suffered from continuous fever. There was one and three-quarters inches of shortening on the affected side, and about the hip-joint there were half a dozen sinuses leading to dead bone. The head of the femur had apparently entirely disappeared by absorption, and it was also evident that the ilium had become considerably involved. The sinuses were freely laid open, the dead bone was removed, and the wounds were carefully dressed. This operation proved unsuccessful, however, and two months later an amputation at the hip was done in order to save the boy's life. The section of the soft parts was made at a high point, all diseased tissue was removed, and the wound was left wide open, so that any recurrence could be at once detected. The acetabulum was found to be perforated; it was thoroughly curetted and its border was cut away with the rongeur. The child made a good recovery from the operation, which was done on March 4, 1899, and immediately began to gain flesh and strength. The wound had to be curetted once after the operation and then healed without further trouble. The boy had been entirely well ever since. The second patient shown was a man of thirty, who had also suffered from tuberculous hip-joint disease since early childhood. Under careful treatment, the use of an extension apparatus, etc., he had enjoyed long periods of immunity from severe symptoms, although the joint had become stiffened and useless. When he was nineteen years old, an abscess of the joint developed, which was opened and healed after seven months. Nine years later he had another ab-

scess formation, which never closed. When this patient came under Dr. McBurney's observation in April, 1897, there were numerous sinuses about the joint. The man was greatly emaciated and suffered much pain; he also had a fever which was more or less continuous. His condition was such that a radical operation for the removal of the diseased tissue was necessary in order to save his life. A high amputation of the hip was accordingly done on May 1, 1897. It was followed by an immediate improvement in the patient's general condition; his fever disappeared and he rapidly gained flesh and strength. He gained eighteen pounds within three months after the operation and had enjoyed perfect health ever since. He wore an artificial limb, the upper section of which was very ingeniously devised by himself; it was firmly attached to the stump and body, and it allowed him to sit down or walk with comparative ease. He walked about four miles daily. Dr. McBurney said that in both of these operations the amount of blood lost was trifling. Hemorrhage was controlled by making a small incision through the abdominal wall at about the point which was usually chosen in operating upon the appendix. Through this incision an assistant's finger was introduced, and the common iliac artery was firmly compressed. This method was preferable to the use of pins or the tourniquet, especially in this class of cases, as it left the field of operation free and the incision could be carried up as high as was deemed necessary. The speaker added that he did not present these two patients as examples of what should be done in many cases of tuberculous hip-joint disease. Such a radical measure as amputation should be done only as a last resort, after conservative treatment had been given a thorough trial and had failed, and the life of the patient had become endangered by the symptoms—continuous fever, emaciation, etc.—which the disease had given rise to.

Dr. Gibney said he agreed with Dr. McBurney that amputation was necessary in advanced cases of tuberculous hip-joint disease with extensive suppuration and severe constitutional symptoms. In these cases there was not infrequently an osteo-myelitis of the femur, with severe pain, which was not cured by mere excision. In such instances, Dr. Gibney said, he had at times tunnelled the femur down to the lower epiphysis and made a counter-opening, and in only one case was the result satisfactory. By resorting to amputation in such a case, the comfort of the patient was increased and his life prolonged. In these cases one was apt to wait too long before advising amputation.

The Early Diagnosis of Mammary Tumors.—By Dr. George F. Shrady (see page 121).

Dr. William T. Bull said that most surgeons were in accord with the views expressed by Dr. Shrady. One very valuable aid to diagnosis he had found to be exploratory incision and the removal of a section of the growth for immediate examination by means of the freezing microtome. Dr. Bull said that all breast tumors could be easily separated into two classes: one in which one was reasonably sure of the diagnosis, and another in which a doubt existed. In the latter class of cases one should not wait for the development of further symptoms, but should make an exploratory incision at once, with the aid of an expert pathologist.

Dr. McBurney said the importance of early diagnosis in these cases could not be emphasized too strongly. The fact was not sufficiently appreciated by the general practitioner that the time to cure the patient was when the disease was very recent. The general practitioner frequently made one of two mistakes: he either regarded the tumor as innocent when it was malignant, or he made a diagnosis of malignant disease, but thought the time had not yet come for an operation. In both instances he was taking a position which did not belong to him in any sense—no more than it would belong to a surgeon to decide when the time had come for a patient with pulmonary tuberculosis to adopt this or that method of treatment or go to this or that climate. Dr. McBurney said that in doubtful cases of mammary tumor he was fully in accord with what had been said regarding the advantage to be gained from an exploratory incision and an immediate pathological examination by an expert, but in order to avoid error, the expert called in should really be an expert. The number of so-called expert pathologists multiplied so rapidly that one must be very careful as to the quality of the expert. Dr. McBurney said he looked upon enlarged glands in the axilla as a very important symptom of malignant disease. Of course, they occurred in other diseases also, but in such cases the character of the disease was usually very plain, whereas if the character of the disease was in doubt and the glands were enlarged, it was quite the rule that one had carcinoma to deal with.

Dr. Robert F. Weir said he had used in the obscure cases the exploratory incision for a number of years as an aid to diagnosis. He agreed with Dr. McBurney that one must be careful in the choice of an expert pathologist, and, furthermore, that the portion of tissue which was submitted for examination should be taken from the growth itself (for in this he had seen errors committed) and that it was sufficiently large. If a very small section was removed, the pathologist was apt to be puzzled. Even under the most favorable conditions, however, the opinion of the pathologist evolved by the hasty method could not always be absolutely relied upon. Moreover, after the removal of a section of a suspicious growth, great care should be taken in closing up the wound in order to avoid the inoculation of malignant tissue which might occur in the wound of the operation that might be subsequently undertaken. In carcinoma, Dr. Weir said, the enlarged glands had a peculiar feel which the educated touch could not mistake. It was a symptom which when present was very valuable, and which when absent often gave a misleading hope to the general practitioner that the tumor was not carcinoma, but we should bear in mind that enlarged glands in the axilla were present in about forty-seven per cent. of those cases in which none were to be felt through the skin. In such cases they could be detected after the axilla was laid open. Dr. Weir said that the supraclavicular incision which some surgeons were now resorting to in order to detect enlarged glands in the neck could sometimes be avoided by simply passing the finger up under the clavicle from the wound made in the removal of the breast and axillary glands and searching for them in that way. By this method a good exploration might often be made, and if a negative result was obtained, a considerable incision might be saved to the patient.

Dr. T. Mitchell Prudden said that while the examination of a frozen section of a suspicious mammary growth, made just previous to an operation, was a very useful method in some instances, there were many cases in which even the so-called expert pathologist could not arrive at a positive diagnosis. Given a reasonably large section of a tumor, which was well fixed and stained, and any experienced pathologist could usually attach a name to it; but when a specimen was hurriedly prepared, some of the structural details were necessarily lost and a positive opinion as to its true character was often difficult, if not impossible. In any event, it should be remembered that the report which the pathologist furnished was not necessarily a diagnosis of the tumor, but only of the portion of tissue sent to him.

Dr. Beverley Robinson called attention to the undesirability of operating upon patients of advanced age who were suffering from the scirrhus type of mam-

mary tumor. The speaker said he knew of two such cases in which the patients were advised against operation by the surgeon.

Dr. Shrady, in closing, said the exploratory incision in doubtful cases, as mentioned in the paper, implied the securing of a section of the growth for immediate pathological examination. This, of course, should always be taken advantage of. He was not surprised, however, to hear Dr. Prudden say that the report of the pathologist could not be relied upon as final in all cases. The speaker said he could recall two instances in which the pathologist's report proved to be entirely erroneous. He believed that the clinical history, gross appearances, and microscopic findings should in all cases be taken into account together. Dr. Shrady said that in cases of atrophic cancer in old women, to which Dr. Robinson had referred, he was rather inclined to advise against operation, as the natural tendency was to die of something else. In three such cases in which he was induced to operate by the constant importunity of patients desirous to take the risk, the disease soon recurred in an acute form and the patients died within a few months after the operation from extensive infiltrations in surrounding parts. In regard to the infiltration of the axillary glands it was universally admitted that such a condition was always confirmatory of suspected cancerous disease; he wished to discuss only those obscure cases in which there was a reasonable doubt of malignancy in the absence of other well-known phenomena.

NEW YORK ACADEMY OF MEDICINE

Stated Meeting, January 17, 1901.

Robert F. Weir, M.D., President.

Portrait of Austin Flint, Sr.—Dr. E. G. Janeway presented this portrait to the Academy, together with a fitting historical sketch of the life of Dr. Flint.

The Value of the X-Ray in Medicine.—Dr. Francis H. Williams, of Boston, read this paper. He said that he had made use of a static machine with eight plates, each six feet in diameter. With such a machine the heart of man could be seen at a distance of fifteen feet. The apparatus should have an adjustment for readily turning the light up and down. Objects could often be made out in a moderate light which would escape observation in a very strong one. This adjustment was especially necessary when the chest was examined for signs of early tuberculosis. Only within the past few weeks had such an apparatus been on the market, having been placed there by his associate, Dr. Rollins. By means of radiographs physicians could determine the presence of calcification in many of the arteries, even of the aorta itself in certain cases. It was also possible under favorable circumstances to distinguish fatty tissues. In the abdomen a portion of the outlines of the dense organs, such as the liver and spleen, were best seen by distending the intestine with gas or air, as this produced a greater contrast; or, the subnitrate of bismuth might be mixed with bread and milk and given to the patient. The outlines of the pelvis could be followed by means of radiographs and its transverse diameter determined more accurately than ever before. In examinations of the chest the patient should be seated in a suitable chair or should lie down on a stretcher. The light should always be at a distance of about three feet from the fluorescent screen, and in examinations of the chest at the point where a line joining the nipples crossed the median line of the body. Thus, observations made at intervals could be compared with one another or examinations on the same patient made by physicians in different localities could be compared. Fluorescent screens were better than radiographs for such work. In order to judge of the density of the lung one must estimate not only the amount of light coming through the chest, but comparison should be made of the two sides of the chest. In emphysema the thorax would be found lighter throughout than under normal conditions. The excursion of the diaphragm was also much lower and more restricted. The heart changed its position very little between expiration and inspiration in such cases. In early tuberculosis the excursions of the diaphragm were shortened on the affected side and the heart was drawn a little to the affected side. In addition, there was found an appreciable increase in the density of the affected side. A photograph was shown of a case of pneumonia on the seventeenth day, that is, at a time when several physicians had been unable to detect any physical signs of the disease remaining, yet this picture showed that there was a very decided increase in the density over the affected side. If an *x*-ray examination showed that the outlines of the diaphragm could be readily made out on both sides, one could be sure that there was no pleuritic effusion present; if, on the other hand, these outlines were indistinct on one side it was probable that the partial obscuration was the result of such an effusion, though it might arise from other causes. By *x*-ray examination it was possible in some cases to determine the borders of the heart more accurately than had been possible hitherto. In some cases of valvular disease or of renal disease it was no longer possible to see clearly the outlines of the diaphragm or of the lower part of the heart, owing to the presence of œdema of the lungs. In central pneumonia it was practically always possible by *x*-ray examination to make out the increased density of the centre of the lung, even though this could not be detected by auscultation and percussion. Empyema following pneumonia was often overlooked, but if an *x*-ray examination were made such an error would not be likely to occur. The *x*-ray examination was of special service in two kinds of cases of aneurism, viz., those in which the aneurism did not present well-marked physical signs, and in a not inconsiderable number of cases of supposed thoracic aneurism which the *x*-ray examination proved not to be of this nature. New growths in the chest were sometimes, as was well known, very difficult of recognition by ordinary physical examination. An *x*-ray examination would enable one to detect such a growth earlier and determine its position and size. The dangers of *x*-ray examination lay in faulty methods and wrong inferences, and were not inherent in the method itself. Among the thousands of *x*-ray examinations made at the Boston City Hospital and at his office there had not been a single case of *x*-ray dermatitis. The method, like other methods of precision, required experience and skill for its successful employment. No mode of examination was more difficult of execution because of the time consumed and the experience necessary rightly to interpret the results of such examinations. A physician who would carefully study one thousand cases, both by the ordinary methods of physical examination and by the use of the *x*-ray, would find his skill in physical diagnosis materially improved. Dr. Williams said he did not wish to be understood as advocating the substitution of this method for any other, but he claimed only that it was an important auxiliary.

The Value of the X-Ray in Surgery.—Dr. Robert Abbe discussed this subject. He said that while there had been an unfortunate tendency to exaggerate the results of *x*-ray examination, it could not be denied that at the present time there were no longer any doubtful cases of fracture, which was in striking con-

trast with the past experience of every surgeon. There was both a negative and a positive value to *x*-ray work in surgery. It was often a positive advantage to say that a shoulder or a hidden point was not fractured. In fracture at the hip joint it seemed to him the *x*-ray examination was superfluous, as nothing could be clearer than the results of an examination with the aid of Bryant's ilio-femoral triangle. In his experience the *x*-ray examination had been most useful in connection with fractures of the shoulder. Again, owing to the great tumefaction about the elbow in cases of injury of this part, an *x*-ray examination would do much to clear up the diagnosis. Formerly the surgeon spoke of only one or two varieties of Colles' fracture; now, as a result of study with the *x*-ray, there were perhaps twenty or more varieties of this fracture. Formerly it had been possible occasionally to set a Colles' fracture very well under anæsthesia; now it was possible under the guidance of the *x*-ray to do far better work in this regard. Formerly certain fractures about the knee had been suspected rather than diagnosed; now they were made as clear as daylight. What had been described years ago as a "sprain fracture" by the English surgeon Mr. Callender, was now known to be a rupture of a ligament with the tearing off of a chip of bone. There was no trouble at all in securing a good radiograph of fractures of the cervical vertebræ, and even determining before operation, and without hurtful manipulation, the amount of encroachment of the fragments of bone upon the vertebral canal. Cases of non-union were also very interesting studies in the light of the *x*-ray. He had had a number of very gratifying experiences with the detection of foreign bodies, such as needles, in the tissues. Such examinations also served to explain to some extent the wandering of needles in the body. A most important point in searching for needles was to make the incision at a right angle to, instead of parallel with the needle. If the incision were made parallel to the needle it was a very easy matter to miss the needle, whereas with the other direction of the incision the knife soon came down upon the needle. He had found radiographs very deceptive in following bullets situated deeply in the tissues.

The Value of the X-Ray in the Detection and Exclusion of Renal and Ureteral Calculi.—Dr. Charles L. Leonard, of Philadelphia, read this paper. He said that renal calculus was generally considered to be much more frequent than ureteral calculus, but his *x*-ray studies had led him to believe that they occurred with about equal frequency. The difficulties of diagnosis by the older methods were well shown by the varying symptomatology of the cases. The *x*-ray method was more definite and precise than any other mode of examination; moreover, it made the operation for the relief of the condition more accurate and allowed of its being made complete. Calculi had been present in both ureters of four patients examined. The method had been demonstrated to be capable of detecting the most minute calculi—a class of cases which were especially dangerous because they were apt to cause much damage and suffering without giving rise to many symptoms. The mortality of nephrolithotomy was only two or three per cent. when done early, but in the later stages, when infection had taken place, the mortality was as high as twenty-five per cent. The *x*-ray examination was made without inconvenience to the patient and without the introduction of instruments into the ureter, with the possibility of causing serious infection. The accuracy of the *x*-ray method had been seriously questioned by some. In one hundred cases he had made a negative diagnosis, and in only one had this diagnosis been set aside by operation, and here the error had arisen from a misplaced plate and a consequently faulty reading of the negative. The only source of error lay in the improper employment of the *x*-rays and a wrong interpretation of the result, and not in the method itself. The reading of the negative was often the most difficult part of the diagnosis. The negative diagnoses made incision into the kidney, and the consequent danger of urinary fistula, unnecessary unless such a procedure was demanded because of some other pathological condition. In two cases the result of the *x*-ray examination had been the only ground for operation, yet this diagnosis had been confirmed by the removal of calculi. The possibility of determining the exact size and position of a calculus enabled one to estimate with fair accuracy the chances of such calculi passing spontaneously, and hence might afford perfectly rational grounds for practising conservatism. The method was most useful also in connection with a litholapaxy to determine if all fragments of calculi had been evacuated. The author's conclusions were based on the study with the *x*-rays of one hundred and thirty-six cases, and the finding of calculi in the ureter in nineteen, and in the kidney in seventeen cases. Numerous skiagraphs were projected on the screen showing calculi in both the kidney and the ureter.

The Technique and Correct Interpretation of Radiographs.—Mr. E. W. Caldwell discussed this phase of the subject. He said that *x*-ray work rarely yielded its best results without the exercise of great patience and much coaxing. The static machine produced a very steady excitation of the *x*-ray tube, and was well adapted for fluoroscopic examination. Static machines of sufficient power for such work were, however, very cumbersome and quite erratic in their action. Probably the most practical form of exciting apparatus, and the one in most general use, was the ordinary induction coil. It was now pretty well established that coils giving sparks about ten inches in length and of considerable energy were the most satisfactory. The ordinary rotary interrupter with a properly adjusted condenser was very efficient and reliable. If mounted on a cushion and enclosed it was practically noiseless. The steadiest and the most powerful discharges from induction coils were obtained by using a liquid and electrolytic interrupter. Interrupters of this class operated with high frequency, and thus permitted a large amount of energy to be taken from a coil of given size. They produced a very steady excitation of the *x*-ray tube—a most important quality. They materially shortened the exposure and diminished the weight and bulk of portable *x*-ray outfits. If the direct electric-lighting current was available at the patient's house he used it with the fluid interrupter; if no electric-lighting current was at hand he ran a lamp-cord out of the window and connected it with the battery of an electric cab. In order to facilitate the arrangement of the patient with reference to the plate it was often necessary to make use of auxiliary appliances of a purely mechanical nature. The table should be adjustable in height and in plane. The movements of the body which accompanied respiration sometimes seriously interfered with the successful making of radiographs. They might be greatly reduced by bandaging the abdomen tightly and instructing the patient to breathe as much as possible with the thorax. Likewise, when a radiograph of the thorax was to be made, the chest should be strapped and the patient encouraged to use abdominal breathing. When an exposure of half a minute was sufficient the patient would usually be able to stop all breathing for that time. It was most important to supplement the fluoroscopic examination with radiographs, for he had seen many cases of doubtful fracture in which the nature of the injury had been made perfectly clear by the radiograph, though it

had been rather obscure when viewed with the fluoroscope.

Within the Reach of the Medical Practitioner.—Dr. Walter B. James said that in the present state of our knowledge it seemed necessary to have a champion for *x*-ray work in medicine. The value of the *x*-ray in surgery was generally recognized all over the world. The work presented this evening by Dr. Williams showed conclusively that with such an apparatus, and with his experience, the *x*-ray examination was most valuable in internal medicine. However, the question arose as to the utility of the method in the hands of the average busy practitioner of medicine. From his own rather limited experience with the method in this field he felt that this branch of study yielded results that repaid the investigator well for the time expended. He was of the opinion that most practitioners could materially increase their facility and accuracy of diagnosis by calling to their aid the *x*-ray. For example, it was often impossible to map out satisfactorily the boundaries of the heart by the old methods of physical examination. Again, the position of the upper border of the liver was often hard to determine by the older methods, though a matter of no little importance in internal medicine.

Skiagraphy of Biliary Calculi.—Dr. Carl Beck said that about fifteen months ago he had had the satisfaction of showing in this same hall to the New York County Medical Association the first skiagraphs ever taken of biliary calculi in the living subject. The patient had been exhibited at the same time. It had been stoutly denied only recently by a German observer that such a feat was possible, but he was glad to say that Dr. Nicholas Senn of this country had been able completely to confirm the assertion that it was a perfectly feasible thing to skiagraph these calculi. It had been supposed at one time that the result depended largely upon the chemical composition of the stones, but later observation and improvements in the technique had demonstrated that it was the method and not the composition of the calculi that was all-important. The vacuum tube for such work must be able to stand a current from a coil giving a fifteen-inch spark. The tube was best tested on the wrist, as this afforded various sorts of tissues. If the lower end of the radius appeared grayish-black and its contour was distinct, and if the soft tissues appeared very light, then the tube was suitable for skiagraphing biliary calculi. A "soft" tube would show the outlines of the radius in intense black and the soft tissues would also be comparatively black, thus lacking contrast. Such a tube might be very good in skiagraphing the hand, but would not do for skiagraphing biliary calculi. When he had visited Professor Roentgen five years ago the latter had advised him not to buy his electrical apparatus in Germany but in America, and had added that the *x*-ray tubes made in Germany were far superior to those manufactured in this country. In skiagraphing biliary calculi the patient should be in the abdominal position. The result was apt to be better if the *x*-rays were sent obliquely, so as not to pass through too much tissue.

SECTION ON MEDICINE.

Stated Meeting, January 15, 1901.

John H. Huddleston, M.D., Chairman.

Some Further Work on the Mosquito-Malaria Theory, with Remarks on the Conditions Around New York.—Dr. W. N. Berkeley read a paper with this title (see page 124).

Dr. William H. Thomson thought this discovery of the true etiology of malaria was one of the greatest in medicine—even transcending the discovery of the etiology of tuberculosis. With the entire removal from our minds of the erroneous conception of poisonous gases and miasms we could look forward to the triumphant doing away with so-called unhealthy climates. There were no such climates *per se*, they being in reality nothing more than infected climates. With the money which the government expended upon one iron-clad the medical profession could contract to render perfectly healthful the most noxious malarial region imaginable.

Dr. Achilles Rose said that while living in Athens he used to sleep outdoors at night. The air was filled with bats and mosquitos, and it had seemed to him that the bats devoured the mosquitos. He would like to know if this really was the case, and whether there were many bats in this country. The question was an interesting one in connection with our present knowledge of the etiology of malaria.

Dr. James J. Walsh said that at Rome four years ago malaria had been looked upon most seriously by the American students there, while last year it had been noticeable that they had already come to feel that malaria had been conquered. There seemed to be no doubt that, with proper precautions, it was perfectly safe for persons to go anywhere in Italy, and that they need not contract malaria, even the most virulent forms found in southern Italy. The only place in which the male and female organisms meet must be in the stomach.

Dr. James K. Crook commented upon the view expressed in certain quarters that malaria had been stamped out in certain very malarial regions by the extensive cultivation of the orange and lemon. He would like to know whether such vegetation was in any way inimical to the growth of the mosquito.

Dr. M. Manges remarked that the Italians had long considered lemon juice one of the great specifics against malaria. He felt sure that the more this research into the etiology of malaria was carried on the more frequently would the æstivo-autumnal form be found in New York City.

Dr. Berkeley said that so far no one had been able to find any mammal or reptile which harbored this parasite so destructive to man.

The Treatment of Influenza.—Dr. William H. Thomson read this paper. He said that while the present epidemic of influenza was fully as extensive as when the disease had first appeared in 1890, it was certainly of a much milder type, and consisted very frequently of nothing more than a catarrh and a fever, with a special tendency to general debility. This change of type he believed to be due to the fact that very few people had escaped from previous epidemics, and that their previous experience had conferred upon them a certain degree of immunity. According to his experience, the disease this year was relatively more severe in children than in adults. He had also noticed that in the few persons who had not previously had the grippe, it was far more severe than the prevailing type. For many years he had looked upon aconite as the best remedy for the aching limbs, observed not only in the grippe but at the outset of many acute disorders. He believed he had often succeeded in aborting an attack of tonsillitis by administering early a dose of aconite sufficient to produce the characteristic effect of the drug upon the throat. This action of aconite was increased by a small dose of Dover's powder. One of the coal-tar series had also proved useful in this class of cases, namely, phenacetin. He would not give it in sufficiently large doses to reduce the temperature. When combined with quinine he was disposed to think that the combination acted as a true antitoxin to the influenza poison. These drugs had seemed to him to diminish the severity of the disease and lessen the tendency to the

development of complications. He had had the greatest success in the treatment of the grippe by the administration of the following: gr. $\frac{1}{6}$ of the solid extract of aconite, gr. i. of Dover's powder, gr. viii. of phenacetin, and gr. vi. of quinine made into two pills. Six pills should be given on the first day, and this dose should be continued daily so long as there was fever, and then should be reduced one pill daily until three were taken. The latter dose should be kept up until all catarrhal symptoms had subsided. One troublesome sequela of the grippe was the paroxysmal cough, which had nothing whatever to do with bronchitis, but was nevertheless very troublesome at night. He had found this would ordinarily yield to gr. xx. of bromide and gr. x. of antipyrin. A very useful measure was to flush out the nose and throat with one quart containing chlorate of potassium and peppermint. Five drops of oil of peppermint should be mixed with ʒ ii. of chlorate of potassium and then dissolved in a quart of very hot water. He knew of no more powerful stimulant to the bronchial muscles than dry-cupping, and hence it was useful as a means of relieving the asthmatic breathing. One should not hesitate to repeat the dry-cupping frequently, but it should be remembered that the weak cupping produced by cups with rubber suction bulbs was wholly inadequate. It was well to follow the cupping by the prolonged application of cloths wet with an infusion of capsicum of the strength of ʒ i. of powdered capsicum to one pint of water. One of the most important things to remember in connection with the treatment of the grippe was that the person attacked should at once go to bed and remain there until well on the road to recovery—indeed, rest in bed alone would carry many cases successfully through the disease.

Dr. Andrew H. Smith said that he had just come from the bedside of a young man suffering from grippe, and had been impressed with a novel symptom—retention of urine. The patient was a healthy young man, and there seemed to be no obvious reason for the retention. With regard to the treatment of periodical neuralgia by ergot, which Dr. Thomson thought so highly of, he said that he was reminded of his experience some years ago with the caisson disease, and its most troublesome and obstinate neuralgia. In the latter nothing had given such prompt and marked relief as full doses of ergot. The annoying and persistent cough so commonly observed after the grippe, had seemed to him to have its seat just at the bifurcation of the trachea. In the few instances in which he had been able to get a view of the bifurcation with the laryngoscope he had found a velvety condition of the mucous membrane at this point. An irritation started here would naturally be intensified by the fact that the impact of the air at every inspiration was received upon this wedge of tissue. He had succeeded best in relieving this annoying irritative cough by the administration of malto-yerbine. Sometimes it was desirable to give the fluid extract of yerba santa in some other vehicle. The vagueness of our knowledge concerning the pathology of grippe made it difficult to lay down any definite rules for its treatment. The great depression resulting from an attack of influenza left the system in a condition peculiarly favorable for an attack of pneumococcus infection, and this explained the tendency to pneumonia. The physician should constantly impress upon his patients suffering from grippe the necessity for respecting the languor which they felt.

Dr. James K. Crook thought that it was wise for persons susceptible to bronchial affections and able to seek a change of climate to leave infected districts. For those unable to leave home he would advise taking daily a small quantity of quinine as a preventive. For persons whose occupations rendered them peculiarly liable to an attack of influenza, it might be well in addition to take half an ounce of whiskey. Another preventive measure which it would be well for physicians to apply in their own persons was the daily irrigation of the nose and throat. For the acute symptoms at the onset of the disease he had obtained the best results from the administration of gr. v. of phenacetin and gr. xx. of bromide of sodium every five hours. When the headache and nervous symptoms were not so marked, good results would follow the use of gr. ii. each of Dover's powder, quinine, and acetanilid. For the annoying cough he made use of a powder containing gr. ii. each of extract of glycyrrhiza and phenacetin, gr. $\frac{1}{6}$ of codeine (or gr. $\frac{1}{12}$ of heroin), and five grains of sugar of milk. In his experience the pneumonia of grippe was always asthenic and required stimulant and supporting measures from the very beginning. For the treatment of the severe muscular pains, the salicylates had proved useless in his hands, and he now simply recommended keeping the body warm and taking an occasional Turkish bath.

A Sure Diagnostic Sign of the Grippe.—Dr. M. Manges said that one could from an examination of the base of the lung posteriorly make a diagnosis of grippe in an early stage. In nearly every case fine dry râles would be heard at the base of both lungs posteriorly, though more marked on the left side in most instances. In his own practice he had been in the habit of applying around the chest once in four hours a warm wet compress. This relieved the cough and made the patient comfortable to a degree hardly appreciated by one who had not given this method a fair trial. He had had a rather large and favorable experience in these cases of teasing cough with heroin, but he would insist that it should be given in small doses and combined with terpin hydrate or with iodide of potassium. The speaker went on to say that life insurance companies had been astounded at the large percentage of cases of albuminuria coming under observation since the grippe had been introduced into this country. Possibly the explanation was to be found in the liberal and almost reckless use of the coal-tar products in the treatment of this disease. In the present epidemic the frontal sinuses and the antrum had frequently been involved. Grippe patients often reinfected themselves by improper ventilation or remaining too long in one room.

Albuminuria and Grippe.—Dr. Brandreth Symonds said that in the first and very severe epidemic of grippe in this country he had found that one in every ten apparently healthy persons applying for life insurance had a transient albuminuria. He understood that cystitis had been especially frequent in the present epidemic.

Carbonic Acid Gas in the Grippe.—Dr. A. Rose thought there should be no surprise at the frequency of hypostatic congestion and pneumonia in grippe cases, for it was comparable to the hypostatic pneumonia occurring in old or greatly debilitated persons. He wished to advocate once more the claims of the carbonic-acid-gas bath for the treatment of grippe. It was surprising how great was the benefit derived from such a bath. The carbonic-acid-gas douche in the nose would give as much relief as cocaine to the coryza.

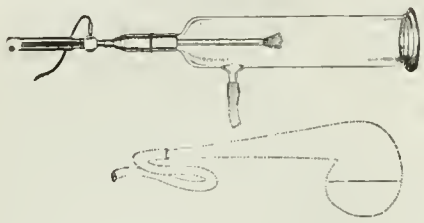
Diagnosis of Sarcoma of the Testicle.—The features that distinguish sarcomatous from other enlargements of the testicle are: (1) Continuously progressive solid enlargement without inflammation; (2) unequal resistance of the swelling at different parts; (3) entire absence of translucency; (4) tendency to become adherent; (5) increasing aches or painfulness; (6) enlargement of the cord and, *a fortiori*, of the lumbar glands.—Jacobson.

New Instruments.

STATIC CATAPHORESIS.

By R. V. WAGNER, M.D.,
CHICAGO, ILL.

Much attention is being given to the use of static electricity as developed by a static machine running at a high rate of speed. For many purposes the current thus developed is of special value and its latest application for the cataphoresis of gaseous substances, such as volatilized mercury, formaldehyde, oil of cin-



namon, etc., has proven to be a most effective means of applying such remedies direct to the diseased tissues and is an ideal treatment for consumption, tuberculous joints, glands, or any local infection. I have lately invented and perfected an instrument which makes the use of static cataphoresis most convenient and will enable any one having a static machine to avail himself of this new and effective mode of treatment.

The instrument consists of a glass cylinder made to fit closely to the skin at one end, while the other is fitted with an adjustable discharge brush; the brush should be attached to the positive pole, while the patient is in contact with the negative. The discharge of current, passing from the brush to the patient through gases or medicated air (which may be admitted to the cylinder through an opening leading to a retort or other receptacle by rubber tubing), drives the substance in with much greater penetration and in a form more suitable than any other known means of cataphoresis.

A NEW EXPRESSION FORCEPS.

By JAMES COLE HANCOCK, M.D.,
BROOKLYN, N. Y.

An instrument so simply constructed and so obvious of purpose as the one represented in the accompanying cut, needs little description. For the past few years I have been greatly interested in the surgical treatment of trachoma and in the various mechanical appliances brought forward with this end in view, especially the many forceps. Having used all the

different forceps and finding that all engage the conjunctiva to an undesirable and injurious extent (this is even true of the roller forceps when clogged with blood), it occurred to me that opposed cylinders of moderate size and absolute smoothness would overcome the difficulty, hence I present this instrument.

43 Cambridge Place.

Severe Anæmia.—In the treatment of severe anæmia I should place rest as of first importance.—Dr. W. N. Sherman, *Medical Age*, November 25th.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 19, 1901:

	Cases.	Deaths.
Tuberculosis	272	191
Typhoid fever	44	11
Scarlet fever	302	22
Measles	102	3
Diphtheria	302	49
Smallpox	9	5

Smallpox in Paris.—One result of the Paris exhibition is, according to the *Semaine médicale*, a threatened epidemic of smallpox in Paris. The disease which caused only four deaths in that city in 1899 and fifteen from January 1st to the end of May of the present year, began to increase in prevalence in June. The number of cases and deaths has, since that time, increased week by week to such an extent that, in the week from October 28th to November 3d, there were fourteen deaths from smallpox. The total mortality from this cause during the period of the exhibition from June to November was just one hundred as against fifteen in the first five months of the year. The prefect of police has ordered notices to be placed on the walls of Paris, calling public attention to the danger and pointing out the measures taken by the administration for the check of the epidemic, namely, gratuitous vaccination or revaccination.—*British Medical Journal.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended January 19, 1901:

		Cases.	Deaths.
Smallpox—United States.			
California, Oakland	December 29th to January 5th	1	
Connecticut, Bridgeport	January 7th	3	
Illinois, Cairo	January 5th	8	
Chicago	January 5th to 12th	19	
Kansas, Wichita	January 5th to 12th	6	
Maryland, Baltimore	January 5th to 12th	1	
Massachusetts, Springfield	January 5th to 12th	1	
Minnesota, Minneapolis	December 29th to January 5th	1	
Winona	December 29th to January 5th	30	
N. Hampshire, Manchester	January 5th to 12th	21	
New York, New York	January 5th to 12th	17	3
Ohio, Ashtabula	January 5th to 12th	4	
Cleveland	January 5th to 12th	51	
Pennsylvania, Philadelphia	January 5th to 12th	..	1
Tennessee, Memphis	January 5th to 12th	8	
Nashville	January 5th to 12th	5	
West Virginia, Wheeling	January 5th to 12th	1	
Smallpox—Foreign.			
Austria, Prague	December 22d to 29th	12	
Canada, New Brunswick, Port Elgin, and Cape Tarmentine	December 28th	40	
England, Leeds	December 29th to January 5th	1	
London	December 22d to 29th	1	
India, Bombay	December 4th to 18th	..	3
Calcutta	December 1st to 15th	..	81
Karachi	December 2d to 16th	16	2
Madras	December 8th to 14th	..	1
Mexico, Vera Cruz	December 29th to January 5th	4	2
Russia, St. Petersburg	December 15th to 22d	5	1
Yellow Fever.			
Cuba, Havana	December 29th to January 5th	..	5
Matanzas	December 29th to January 5th	1	
Mexico, Vera Cruz	December 29th to January 5th	1	
Cholera.			
India, Bombay	December 4th to 18th	..	6
Calcutta	December 1st to 15th	..	56
Madras	December 8th to 14th	..	1
Plague.			
China, Hong Kong	November 24th to December 1st	..	2
India, Bombay	December 4th to 18th	..	178
Calcutta	December 1st to 15th	..	39
Turkey, Constantinople	January 11th	*

RADICAL CURE OF INGUINAL HERNIA.[1]

BY A. M. PHELPS, A.M., M.D.,

PRESIDENT NEW YORK STATE MEDICAL SOCIETY, 1900–1901.

GENTLEMEN: I appreciate the very great honor which you have conferred by electing me to the highest position in the gift of the Medical Society of the State of New York, and it is with the profoundest feeling of appreciation and pleasure, mingled with no small degree of misgiving, that I attempt to-day to deliver the ninety-fifth annual address. The misgiving which I feel is due to the fact that the annual address has almost always been upon the broad subject of medicine or surgery, marking the advances that have been made in either during the last century or centuries. But the subject has been thoroughly covered in many of the addresses which I have examined, and which appear from time to time in our periodicals. I feel it would be simply threshing over old material —the review of which might be interesting, but which would add nothing to what has already been published —hence I resolved to present to-day the subject of "The Radical Cure of Inguinal Hernia."

There is probably no surgical affection which has commanded attention from the profession, or wrought more disaster to the human family, than inguinal hernia. When we remember that for hundreds of years no rational operation had been attempted for the relief of strangulated hernia; and, knowing full well the frequency of that dangerous malady and the frightful mortality, amounting to more than seventy-five per cent. when not treated surgically—we can fully appreciate the importance of preventing the occurrence of strangulated hernia by a rational operation before strangulation takes place.

For more than two thousand years, surgeons of every decade and century have proposed and performed operations based upon some theory or other to prevent the descent of the intestine into the inguinal canal, always meeting with a signal failure; and it may seem strange, but still it is true, that not until twelve years ago was any operation performed that would receive one moment's consideration to-day from any surgeon who is familiar with the subject.

Bull reported one hundred and thirty-four cases in 1890, and confessed that his "observations go to strengthen the conviction that all methods of radical cure will be found unsatisfactory." And this experience of Bull was the experience of all surgeons. Bull followed Socin's method; that is, excision of the sac after ligation; then Banks' method: excision and ligation of the sac with suture of the pillars of the external ring; then, subsequently, the entire canal was stitched up after the sac was ligated and excised. He reported twenty-seven per cent. of relapses within the year after the first operations; forty per cent. from the second method; and forty-two per cent. from the third. He states that:[2]

"As to results being no better by the complicated method of the suture of the ring alone or of the ring and canal, than by the simpler method of excision of the sac after ligature, I shall confine myself to that method of operation until other procedures which have stood the test of years make a more promising showing." From a series of one hundred and thirty-six cases there remained only four which had been over four years without recurrence. In his second paper Bull further states:

"Now that ten years have elapsed since the modern surgical operations have been in vogue, we ought to hear of, or have presented to us, patients who have been more than five years at the least without relapse. We could naturally expect to see such cases occasionally at a special hospital; but there are none such."

We will return to the consideration of modern operations after first glancing at

A Brief History of the Operations for Hernia.—The history of the operations for hernia has a direct bearing upon modern methods. So far as the literature upon the subject can be traced, Celsus appears to be the first who attempted an operation for the cure of hernia in the first century. His description of his methods is very vague, but he seems to have understood the anatomical and mechanical principles accurately. He made a free incision down upon the hernial sac and pushed the omentum back. The sac was then tied off and the wound closed. The probabilities are that he stitched together the pillars of the ring and all of the soft parts. His operation, however, was confined chiefly to children. He seldom performed it on patients in adult life.

Heliodorus, one hundred years later, describes an operation which he performed, one very similar to that of Celsus, and closely resembling nearly all the modern operations. He says[1] that

"We must cut off the hernial sac with great care. If we take off less than is protruded the result will be the production of a new hernia, for the edges of the wound will be slack, and the way prepared for the slipping out again of the intestine. If one resects more than is protruded, then the hernia will recur, for the edges of the peritoneum, because of the too great resections, cannot be brought together and the patient is in danger, because the normal parts have been taken away."

So we see that he was fully alive to the fact that if the peritoneum and transversalis fascia retracted, a weak point was left in the abdominal wall; and it is for this very reason that in my writings I have described this accident which I have observed post mortem after ligation of the sac, and have advised surgeons never to think of ligating the sac, because the ligature is likely to cut through the peritoneum and transversalis fascia, allowing them to retract, leaving a large surface exposed with no fibrous material to prevent the escape of the intestine. Instead of ligating the sac, it ought always to be cut off and stitched up, exactly as is done in any other abdominal wound. This operation of Heliodorus is certainly as efficacious as any of the modern operations up to 1888 and of many that have been performed since that day.

[2] Bulletin of the Johns Hopkins Hospital, vol. iv., 29, 1893.

[1] "Lehrbuch der Chirurgie," Bd. iii., Edward Albert.

Dr. Henry Bryant, of Boston, published in 1846 a "Treatise on the Radical Cure of Inguinal Hernia," for which the Boylston prize was awarded the author. I am indebted to that treatise for many valuable historical facts.

Up to 1846 cauterization, ligation of the sac and spermatic cord subcutaneously, suturing of the canal and the sac either subcutaneously or through an open wound, excision of the whole or part of the sac, castration together with the actual cautery applied to produce sloughing of the parts, are vividly described. Caustics were applied to the skin just over the external ring; the skin, the sac, and sometimes the periosteum were destroyed, which produced exfoliation of the bone. It was supposed that the scar which followed would be sufficient to prevent relapse. This idea that scar tissue would prevent relapse was the fundamental principle in McBurney's operation.

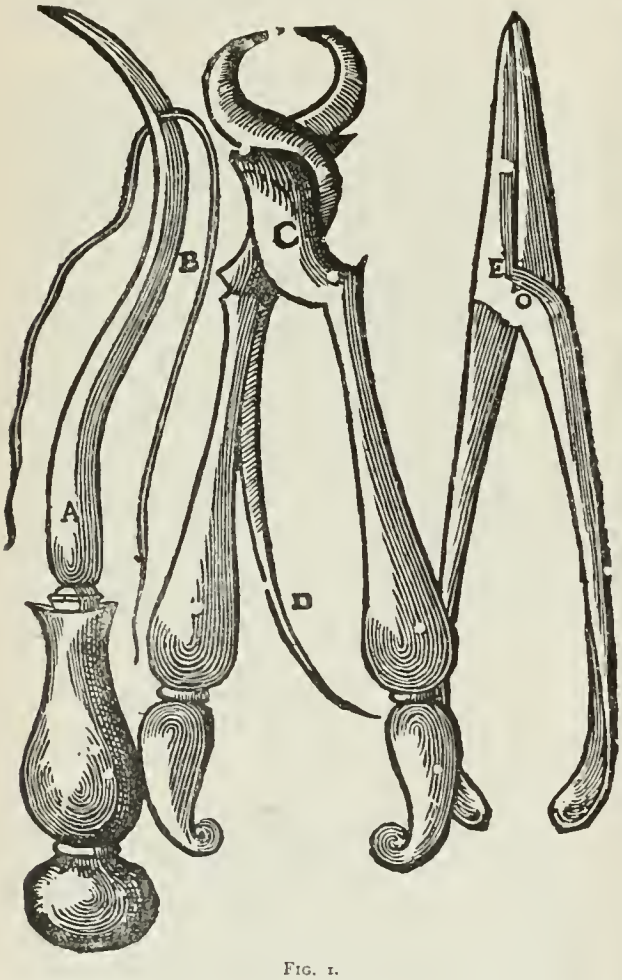

Fig. 1.

Subsequently, an incision was made down and a caustic was applied to the neck of the sac. This barbarous treatment resulted in a very great mortality and relapses always followed.

A red-hot iron was applied over the external ring, burning deeply to the bone. This was a favorite operation during the early part of the Christian era and also during mediæval times. Ligatures were applied in different manners—subcutaneously or after an incision had been made.

These ligatures, as they were passed around the sac either with or without the cord, were tied with pieces of wood which were placed over the integument, and the pressure induced sloughing, and of course in due time the ligature came away. It is needless to say that all these operations were attended with a high rate of mortality and relapses always occurred.

Suturing was a favorite method even during the present century. Then came the craze for the removal of the testicle together with the cord and sac, and it is only within, comparatively speaking, recent times that laws were passed in France to prevent this need-

Fig. 2.

less mutilation. Paul of Aegina in the seventh century was probably the first to introduce the idea of castration. He removed the testicle, the cord, and the sac. The barbaric methods of mediæval times were much employed by the Arabians, but were not fully endorsed by Ambrose Paré, who discarded many of these methods. He, however, employed the subcutaneous ligature (see Fig. 1).

Fig. 2 illustrates the method of applying the double and single truss by Ambrose Paré either before or after an operation for hernia. The principles are correct and they might be applied with profit and benefit by modern truss fitters.

Subcutaneous ligation of the sac has been used by eminent surgeons during the nineteenth century, and they have claimed brilliant results. The mortality has been placed as high as seven per cent. These ligations are performed either through an open wound or subcutaneously at the external ring.

It was not until the sixteenth century that a cutting operation was done for incarcerated hernia. This was

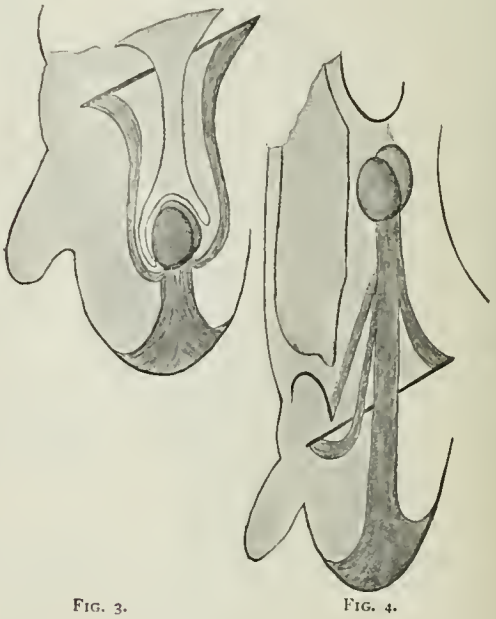

Fig. 3. Fig. 4.

performed by Pierre Franco, an uneducated rupture and stone cutter. From his day until the beginning of the present century, surgeons have from time to time performed his operation.

Sir Astley Cooper certainly comprehended all there was of the past and of his day in his treatise on hernia,

and no doubt his work has contributed more toward the rational treatment of strangulated hernia than that of any other surgeon.

We find the profession, which accepted the operation during the century, divided about equally on the questions whether the operation should be performed as an extraperitoneal or as an intraperitoneal operation.

Another favorite method was the introduction of foreign bodies into the hernial sac, the object being to produce a mass of new inflammatory material, which would prevent the descent of the intestine. The injection of irritating fluids within or outside of the hernial sac became a favorite method. But of all the methods of mediæval times, the one that has survived is subcutaneous suture, which has been practised almost up to the present time in Great Britain and Italy. In 1882 Dr. J. H. Warren wrote a book advocating the injection method, which is essentially the same as Heaton's. The injection of alcohol is quite popular at the present time among certain sur-

Fig. 5.

geons in France. The introduction of antiseptic surgery has played a very important part in revolutionizing the operative methods for the cure of inguinal hernia, and following upon it was an operation resembling very closely that of Heliodorus; that is, ligation of the neck of the sac with extirpation and the closing of the canal.

In 1804, J. C. Warren first began to operate upon strangulated hernia, applying methods which he had learned from Sir Astley Cooper, but he met with the greatest of opposition from the profession, and it was not until years after that the proper plan of operating for strangulated hernia was accepted by the profession of America. It is due to the work of Sir Astley Cooper and J. C. Warren, of Boston, that the operation for strangulated hernia was accepted by the profession of Europe and America.

Dr. Henry O. Marcy, of Boston, seems to have been the first to operate upon strangulated hernia in 1871 using antiseptic methods and absorbable buried sutures of catgut. Czerny, Annandale, and Steele had already operated upon hernia following closely the methods of Heliodorus, when Marcy operated upon a case of non-strangulated hernia in 1878. We must give to Marcy the credit of introducing the absorbable catgut suture and the antiseptic precautions introduced by Lister. In the Vienna *Medicinische Wochenschrift*, 22, 1877, are reported the first seven cases of Czerny.

Fig. 6.

He ligated the sac and stitched up the pillars of the ring, which he sutured with catgut, with drainage. Czerny's, Marcy's, Steele's, and Annandale's operations all seemed to be very similar. The chief point in the operation was the ligation of the sac, and stitching up the pillars of the ring. Macewen's opera-

Fig. 7.

tion was similar, except the treatment of the sac, which was folded up over the internal abdominal ring. All of these methods have been tried by Bull, Weir, and other surgeons, but relapses have been so frequent

that in this country they all have been abandoned. Kocher's operation differs from all others in one respect—he brings the sack out though an opening in the external oblique and cuts away a large portion of the sack before transplanting.

In the transaction of the American Medical Association for 1852, volume v., will be found a very interesting account of the status of the operation for hernia published by the committee appointed by that association, the chairman of which was George Hayward, of Boston, to inquire into the various methods of operation. In answer to a circular letter sent out by the committee Heaton refused absolutely to give a description of his method of injection; Watson, of New York, used the subcutaneous method as recommended by Pancoast; Eve, of Augusta, Ga., introduced pins, according to the method of Bonnet, a portion of the scrotum being invaginated; Heminway, of Derby, opened the sac and brushed it over with tincture of iodine on the inside after reducing the contents of the sac; Pond, of Griggsville, cured all of his cases by pressure, and Merriam, of Topsville, Mass., removed a portion of the omentum in femoral hernia.

Still, in all of them there had been learned a very important lesson, and as time went on there was a better conception of the requirements of an operation, until finally there were introduced to the profession others which come the nearest to perfection of any. I allude to Bassini's, Halsted's, and an operation the description of which I published in 1894, and which I will present to you to-day.

Bassini in March, 1888, reported one hundred and two cases before the congress of Italian surgeons,

Fig. 8.

describing his operation, which was the beginning of a new era in the radical operation for hernia. He believed that the cord played a very important part in producing relapse. Therefore, to obviate this important factor, he transplanted it through the transversalis and internal oblique muscles, stitching up these two muscles underneath the cord, after which the aponeurosis of the external oblique was stitched over it, together with the skin and cellular tissue. There is no doubt that Bassini was the first to recommend the transplantation of the cord in the operation for hernia, and his stitching was done with absorbable catgut.

I shall consider these points a little later.

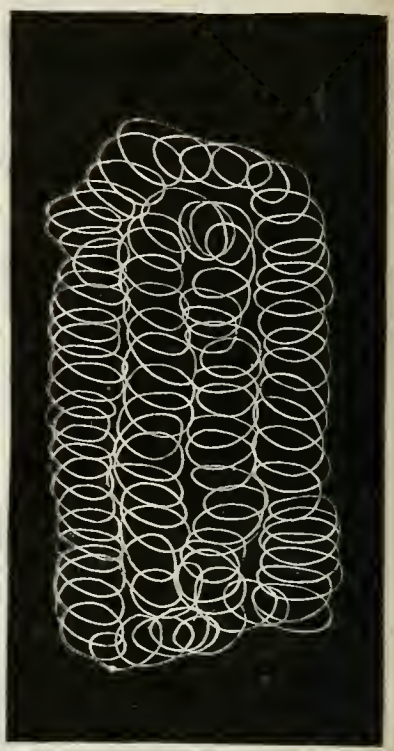

Fig. 9.

In November, 1889, Halsted[1] described his operation. He makes a long incision down upon the sac, extending a considerable distance beyond the internal ring. The cord is transplanted through all of the muscles, and the abdominal cavity is closed by quilted suture passed through the peritoneum at a level higher by one and a half to two inches than the so-called neck of the sac. Then interrupted strong silk sutures, passed so as to include everything between the skin and the peritoneum, are used to close the deeper portion of the wound, which is sewed from the pubis to the outer upper angle of the incision. The cord now lies superficially to these sutures, and penetrates through the abdominal muscles about one inch to the inner side of the anterior superior spine of the ilium. The transplantation of the cord, according to Halsted, is the proper method in my opinion. So we see that there is a vast difference between the operation of Bassini and that of Halsted. In Bassini's operation the cord lies underneath the external oblique, and relapses must occur, and the canal is not so perfectly obliterated, owing to the presence of the cord; whereas, in Halsted's operation, the cord lies external to all of the muscular layers.

In a subsequent paper of Halsted's,[2] he reports a large number of cases in which he resected the veins of the cord. In one hundred and nine cases operated upon by Halsted, in which the veins were excised, he claims there were no relapses. In eighty-six cases in which the veins were not excised he reports that there were eight relapses, or nine per cent. Atrophy of the testicle was observed in a number of cases in which the veins were excised, and it is a question in my mind whether we are justified in submitting the patient to an operation which will result in the loss of a testicle, when by other methods we can surely prevent relapse.

Now, in regard to the results of Bassini's operation. In De Garmo's article,[3] reporting two hundred and fifty Bassini operations, he says:

"Next in importance to its safety, is the consideration of the permanence of the cure. In a paper on this subject, read before this body in 1895, I ventured to predict that permanent cures would be ninety per

[1] See Johns Hopkins Hospital Bulletin, vol. i., No. 1, p. 12, "The Radical Cure of Hernia," by Dr. William S. Halsted.

[2] Johns Hopkins Hospital Bulletin, No. 4, 1893.

[3] Published in the Journal of the American Medical Association, October 2, 1897.

cent. I think this estimate is too low, and do not hesitate to advance it to ninety-five per cent."

Professor Girard, of the University of Berne, stated to me last summer at the time I demonstrated my operation to him, that the relapses following Bassini's operation would fall between fifteen and twenty-five per cent. or even larger. Dr. Kuemmel, of the Eppendorf Hospital, Hamburg, Germany, stated to me that the relapses in his hands from Bassini's operation would be more than twenty per cent. Thus, we have from Halsted himself the statement of the percentage of relapses, and also from other eminent operators, in regard to Bassini's operation. These two operations are based upon the following principles:

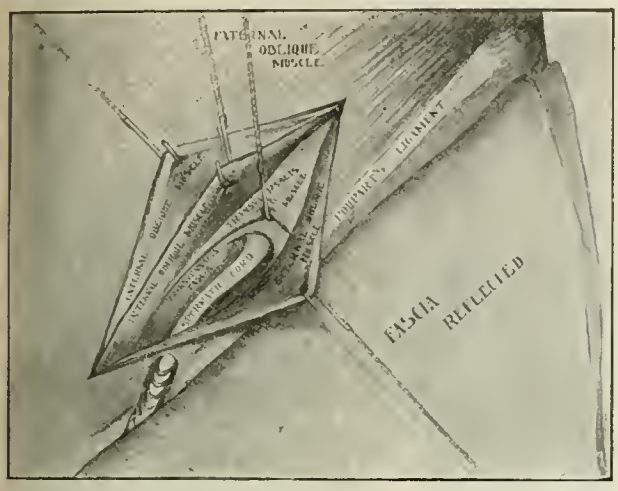

Fig. 10.

That a partial or perfect obliteration of the inguinal canal is important, facilitated by the transplantation of the cord from the canal; and the perfect coaptation of all of the muscles and the union, and the removal of the sac are imperative. Not only stitching up of the pillars of the ring but of the entire inguinal canal should be done. So far as these principles go they are correct, but they do not take into consideration certain anatomical facts that are present in almost all cases of inguinal hernia, especially in adult life. Unquestionably, the early ancestors of the human family were quadrupeds; and their normal position was horizontal and not erect. In them the pressure of the internal abdominal organs was in the hypogastric region and not the epigastric. This accounts for the great strength of the abdominal walls in the region above the umbilicus and the weakness below. At the time of the "fall of man," from the horizontal to the upright position, the viscera, instead of making pressure upon the strong hypogastric region, found themselves impinging against the weakened epigastrium. And then again, by some peculiar freak of nature in the early life of the fœtus the testicle develops behind and below the kidney (see Figs. 3 and 4). Partially organized material extends from the testicle down to the bottom of the scrotum (Fig. 4)—the gubernaculum testis—and by the contraction of this gubernaculum testis the testicle is gradually drawn downward and over the pubis into the scrotum, taking with it a fold of the peritoneum (Fig. 3). This fold of the peritoneum in the normal condition becomes obliterated, leaving the testicle covered with a small sac known as the tunica vaginalis. The very fact that this organ has been dragged down through the abdominal parietes necessarily weakens it. And then again, if by any chance the peritoneal cavity is not obliterated, the intestine finds its way down along the track taken by the testicle, gradually distends the opening, and by pressure destroys the muscular fibres in this region (see Figs. 5 and 6). Or if by violence or from any other cause the intestine is protruded

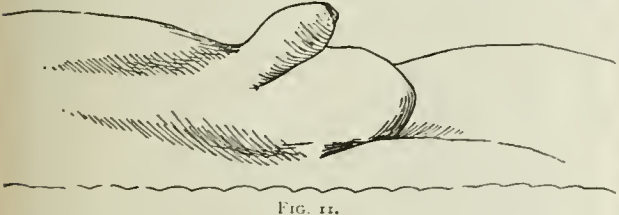

Fig. 11.

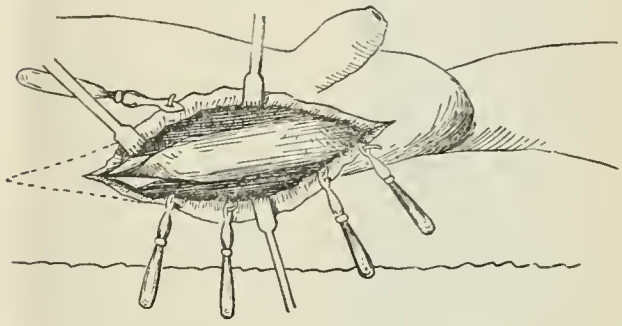

Fig. 12.

downward, carrying the peritoneum with it through the internal abdominal ring, it is bound to destroy or attenuate the muscular tissue in this region, adding to the normal weakness of the parts (Figs. 7 and 8).

Now let me ask you, how is it possible, when destruction of the normal muscular tissue of the abdominal walls has taken place, to unite it in such a manner as to act as a barrier against the pressure from within? It is an impossiblity, and this very fact, together with one other, is the cause of relapse in any form of operation that I have already described. The other reason why relapse takes place is that there is no effort made on the part of the surgeon to reproduce this tissue which has been destroyed by pressure, and to prevent the stretching of connective tissue which always results from wound healing. Even when primary union of tissues, which are to sustain pressure, takes place, the stretching of the connective tissue at the point of union is likely to occur. Then we can readily see why so many relapses follow the operations of Bassini, Halsted, and others.

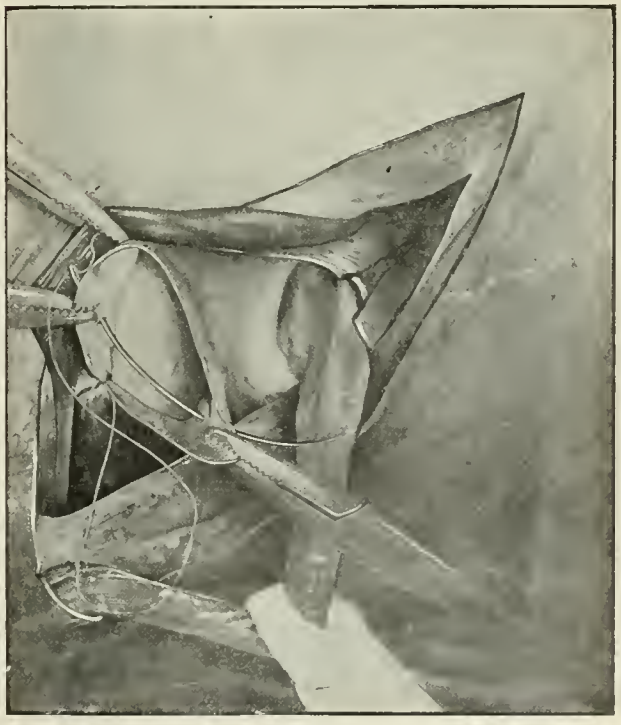

Fig. 13.

McBurney in his operation—which is so well understood by every one that it requires no description here—contemplated the formation of a large amount of scar tissue which was supposed to prevent relapse, but the most lamentable relapses I have seen followed that operation.

In the City Hospital (New York), which is the dumping-ground for all the hospitals of the city, these cases of relapsed hernias following McBurney's and other operations were transferred to us after they had been operated upon from one to five times by our very best surgeons. We were in a quandary as to what should be done with them. Trusses could not be applied, and the best we could do was to adjust large bandages to hold them and make the patient comfortable. My colleagues—Dr. James E. Kelly and Dr. Constantine J. Maguire—and I were constantly attempting to close these hernias, but the effort always resulted in failure. It was the hopeless condition of those unfortunate individuals which led me in 1892 to begin another line of work. I found that when these relapsed hernias were opened the muscular tissue was almost entirely destroyed, and all that was left to deal with were masses of attenuated scar tissue and fascia. I conceived the idea that if I could introduce into the inguinal canal a fine silver wire filigree or mattress (see Fig. 9) and stitch up the canal with a continued suture of fine silver wire after having transplanted the cord through all the abdominal parietes downward and outward where the least pressure would come, I might possibly get reproduction of inflammatory material, and the wire would prevent the stretching of the connective tissue and reproduced material. I operated upon several cases. In the winters of 1892–93 and 1893–94, some of these cases were presented together with a paper on the subject to the surgical section of the New York Academy of Medicine in the spring of 1894.[1] At that time I knew nothing of Halsted's operation, and

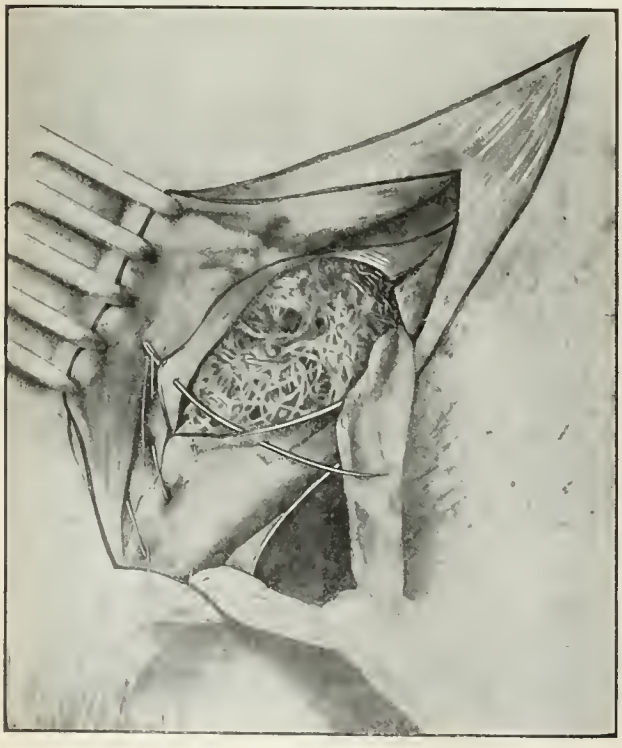

Fig. 14.

Bassini's operation was just beginning to be exploited in this country. The conclusions at which I arrived proved to be correct. That portion of the abdominal parietes became the strongest, and in none of those cases did I see a relapse. It must be remembered that our cases at the City Hospital are from the broken-

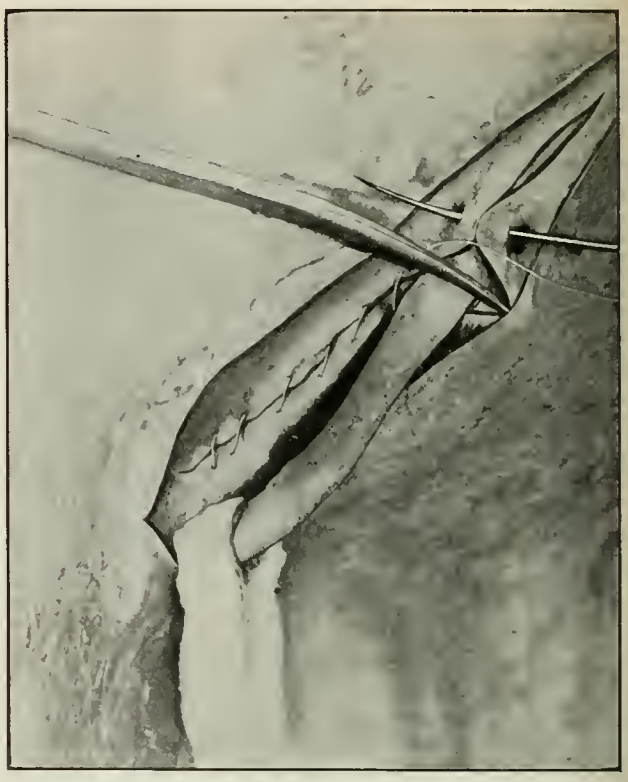

Fig. 15.

down class, usually drunkards and old men with relapsed hernia; certainly the most difficult class to make a favorable record in.

I dwelt in that original paper at great length upon the management of the sac, which I think is of no importance whatever. The ligation of the sac is absolutely wrong, for the reason that the peritoneum and transversalis fascia are likely to be cut through and retract, leaving a large surface uncovered by this dense fibrous tissue.

The folding up of the sac recommended by Macewen, the transplanting of it according to Kocher, the inversion of the sac into the abdominal cavity by the different methods of inversion, which I advocated at that time, I have discarded. In all my abdominal work I have eliminated the use of absorbable suture material, as also did I that of silk, on account of the great difficulty of sterilizing it, and then frequently I was called upon to remove it months after Silkworm gut is a piece of rigid wire that is worse than useless in any soft parts; it nearly always finds its way to the surface. The fine spun silver wire is an ideal suture for closing abdominal wounds. Kangaroo tendon is no better than chromicized catgut; in fact, nine-tenths of the material sold for Kangaroo is catgut.

The use of silver wire is by no means new. It has been used for hundreds of years in surgery, as have also catgut and silk, but the method of using it to make it a success is another proposition. The plan which I employed I am sure is correct, and I have proved it after years of careful work. Agnew introduced wire into gynæcological work nearly half a century ago. Gross had already used it, but they used it in interrupted sutures in hernia, as did also Halsted. This manner of using silver wire is entirely wrong, as it does not become anchored in the tissues, and will certainly, on account of motion, find its way to the surface sooner or later. We introduce wire into bone, and when the ends of the wire are well pounded into the substance of the bone no trouble arises from it. If

[1] See American Medical and Surgical Bulletin, March 15, 1894, p. 365; also New York Medical Journal, April, 1894.

it is introduced by a continued suture into the soft parts, it will give no disturbance whatever. Suppuration is not so likely to occur from the use of silver wire as from any material of which I know. Prof. Schede, of Bonn, Germany, uses the silver wire, as I have described it, both in hernia and in closing the abdominal cavity, as do also other surgeons in Germany.

The statement which is frequently made by surgeons that the wire will cut out is absolutely erroneous when employed as I use it. If the pillars of the ring are stitched together with interrupted sutures it will surely cut out; but with a continued suture, introduced as I will soon describe, it remains permanent, and a great mass of inflammatory material forms about it, which adds to the strength of the abdominal parietes, by producing new organized material, and the wire prevents it from stretching.

Fig. 10 is a drawing made from the dissection of the inguinal region which will explain itself, the internal ring being a hole in the transversalis fascia.

The operation which I first performed in the winter of 1892–93, with the modifications that I have made, is as follows. Fig. 11 represents a central hernia.

An incision is made from a point one inch to the inner side of the anterior superior spinous process to the spine of the pubis (see Fig. 12), and carried down to the sac and to the peritoneum, splitting the entire length of the inguinal canal to about an inch and a half beyond the internal ring. The cord is separated from the sac and lifted from the canal, and the sac cut away (see Fig. 13). The sac is not cut too short, neither is it left redundant. This sac is stitched up with a continued suture of fine silver wire. The transversalis muscle and the internal oblique are separated from the external oblique and stitched together with a continued suture of wire, beginning at the spine of the pubis, closing the canal firmly (see Fig. 14). The muscles are slightly notched external to the internal abdominal ring to allow the cord to pass through without pressure. The third row of sutures closes the aponeurosis of the external oblique,

Fig. 16.

together with the pillars of the ring the entire length of the wound (see Fig. 15), the aponeurosis being notched at the point where the cord makes its exit. Over all, the skin and cellular layer are stitched with catgut. Great care is exercised in stopping all hemorrhage before the wound is closed. After the sac has been stitched up (and underneath all of the muscles) over the entire length of the inguinal canal is placed a fine filigree of silver wire (see Fig. 13). Over this each muscular layer is stitched. The muscles must be perfectly separated one from the other, in order to secure the best coaptation. The skin is stitched with catgut. The cord lies directly under the skin, as in Halsted's operation. Fig. 16 shows the wound closed. In a very fat subject, a small drainage tube is inserted down to the wire, which is removed at the end of thirty-six hours. Three rows of continued wire sutures are used in all herniæ, viz., neck of sack, deep layer of muscles, and external oblique.

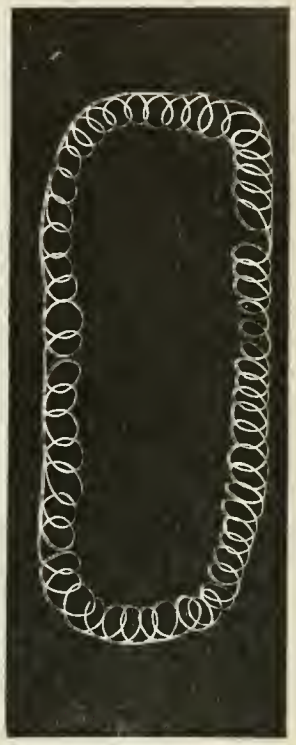

Fig. 17.

In cases of small hernia, instead of putting in the wire filigree or mattress, a few loops of wire (see Fig. 17) are placed directly across the canal over the transversalis fascia and peritoneum, and the muscles stitched over it; or the layers of muscles are closed with a continued suture of fine silver wire, both ends of which are anchored, and all of the ends cut short so as not to irritate the tissues (see Fig. 18). For large openings a wire mattress or filigree is absolutely necessary (see Fig. 9). In all cases of relapsed hernias, when there is atrophy of muscles due to pressure, it is imperatively demanded or a relapse will likely occur. In smaller hernias a few wire loops are sufficient (see Fig. 17); a mattress suture, the two ends of which are fastened firmly in the muscles and the ends cut short, is all that is required, the mattress being omitted. Two rows of these continued sutures are necessary, one for the deep and the other for the superficial layer of muscles. In making these filigrees from ten to a hundred and fifty feet of wire are required, depending on the size of the opening to be closed. .

It has been urged that this wire will cause suppuration. Permit me to say that suppuration is not produced by any foreign body. It is always produced by bacteria. Then for years I have been told that I would have to take this wire out. I have never yet been obliged to do this, with the exception of one or two cases, and these were soon after operation, on account of certain complications arising, not due to the wire.

Fig. 19 is a correct drawing from the photograph of the inguinal canal removed from a patient upon whom I operated, putting in something like twenty feet of silver wire in loops and continued suture. This patient returned to the hospital two and a half years later and died from a hysterectomy. The house surgeon cut out the inguinal canal and presented it to me. I think you will agree that this portion of the abdominal parietes is as strong as any other part of the abdominal walls, at least strong enough to withstand any strain that may be put upon it. The reason for this is that the inflammatory material has become organized, and has been prevented from stretching by wire loops and suturing.

Fig. 21 shows the scars after a McBurney operation;

Figs. 22 and 23 show the proper line of incisions, together with the neck of the sack and also the sack lifted from the canal. I am indebted to McBurney for Figs. 11, 12, 20, 21, 22, and 23. The dotted lines indicate the extent of the incision beyond the internal ring.

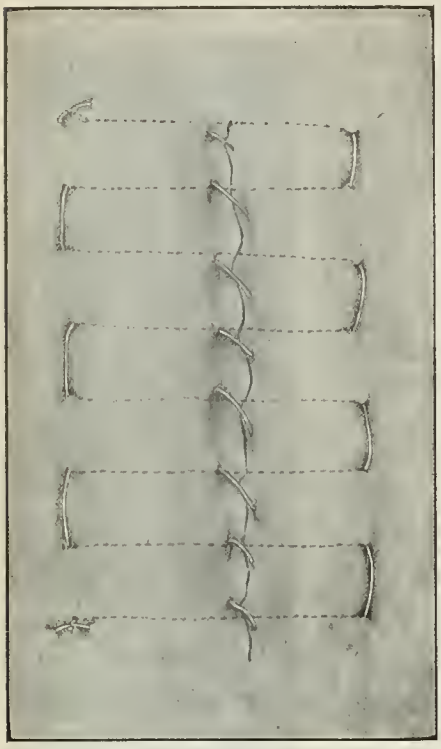

Fig. 18.

In August, 1900, I read a paper before the Thirteenth International Congress, in Paris, on this operation for hernia, and the methods of closing the abdominal wounds with a continued suture of fine silver wire. I then reported two hundred and sixteen operations performed since 1892. Forty-six were relapsed Bassinis, and fifty-one from other operations, chiefly that of McBurney.

Since my return home, I have operated upon twelve other hernias, three of which were relapsed Bassinis, making a total of two hundred and twenty-eight. Understand that these relapses are from the hands of the best surgeons in New York City, many of whom have written extensively upon the operation. Three of these cases are now in the City Hospital. At the time of the reading of the paper in Paris there were sixteen suppurations in the series. Two of my cases in the last twelve have suppurated for reasons which I discovered.

Now the question arises, What will we do with suppurating hernias? Shall we remove the wire? Most certainly not. There have been, in my series of two hundred and twenty-eight cases, eighteen of suppuration. There have been no deaths. These cases of suppuration are simply cleansed out. They are usually found to be a local point of infection superficially or in the wire filigree, and that portion of the wire can be removed, but great care should be taken not to remove the deep suturing, because if this holds there

Fig. 19.

is no tension made on the inflammatory material lying over it. In all suppurating cases which I have operated upon, there were found dense masses of fibrous tissues encysting the wire. These local points of infection have been scraped out and filled with pure carbolic acid, which is left in two minutes, and the wound is then washed out with pure alcohol, then a two-per-cent. solution of pure carbolic acid is used, and the wound is packed. These cases sometimes require a second operation, but with a little patience the tissues will granulate up over the wire, and the parts become firm. Cases of partial and even complete removal of the wire have been reported to me by other surgeons, but no one has reported a relapse. Many of my cases

Fig. 20.—Final Dressing.

I have followed—just what number I do not know. There were thirty cases from 1892 to 1896 that I have seen personally without a relapse. I have asked all the hospitals and dispensaries to report to me any relapsed cases that have been operated upon at the City Hospital, but I have heard of none such.

I have drawn a line of distinction between Bassini's and Halsted's operations. They are both original and each differs from the other. The points of originality in the operation which I have performed are:

1. The reproduction of large masses of inflammatory material to restore the abdominal parietes, and the introduction of a fine silver wire filigree

Fig. 21.

throughout the entire inguinal canal, over the transversalis fascia, which adds to the strength of the weakened abdominal parietes and prevents the new material from stretching.

2. Cutting off the hernial sac, and retreating from the operation exactly as from any abdominal operation, stitching up the peritoneum and transversalis fascia with a continued suture of fine silver wire.

3. The use of fine silver wire with a continued suture. To sterilize the wire, after it has been thoroughly boiled or steamed, I throw it into pure carbolic acid a few minutes before the operation, after which I dip it into alcohol, hold it over an alcohol lamp, and burn the alcohol upon the wire. This sterilizes thoroughly.

Drainage should be avoided if possible; but, if necessary in thick abdominal walls with much fat, a glass drain is the best.

I have closed up all my abdominal wounds since 1892 with fine silver wire, and I have never yet seen a hernia result in many hundreds of cases. In brain surgery, with loss of a large portion of bone, instead

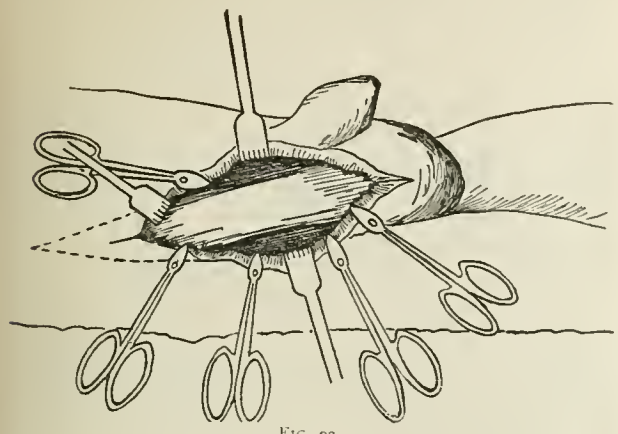

Fig. 22.

of putting a plate over the bone wound I simply stitch from one side of the opening to the other, taking the periosteum and aponeurosis in the suture, then stitch at right angles, making a network, after which the scalp is closed over it with catgut sutures, with drainage.

In rupture of the biceps tendon, I invariably stitch those muscles with fine wire and plenty of it to pre-

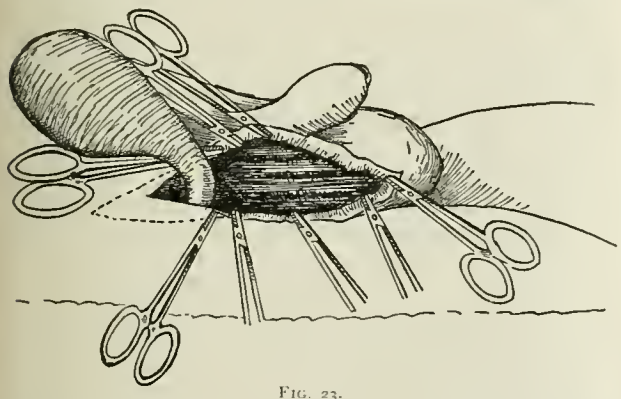

Fig. 23.

vent stretching of the scar tissue. In the reproduction of muscle, instead of using catgut, I stitch between the ends of the muscles, not including the sheath, half a dozen strands of fine silver wire together with fine catgut, and it is seldom that I fail to get a very good reproduction which never stretches.

Finally, in two hundred and twenty-eight operations there were forty-eight relapsed Bassinis and fifty-one following other operations, chiefly McBurneys. Nearly all of the relapsed hernias had been operated upon from one to five times in other hospitals, or by our staff at the City Hospital.

Gentlemen, we have considered the subject of hernia from the beginning of the Christian era down to the beginning of this the twentieth century, and I believe that we have arrived at the last stage of perfection in the technique of the operation for its radical cure.

Surgical Indications in Acute Purulent Ear Disease.—(1) Removal of all obstructive conditions to respiration, and proper ventilation of the tympanic cavity, viz., adenoids, enlarged tonsils, deviated septum, spurs, enchondroses, polypi, and hypertrophied turbinals. (2) Enlargement of the opening in the drum if it is too small to permit free drainage. (3) Opening of the mastoid, if the discharge continues after three or four weeks of persistent antiseptic cleanliness.—Dr. A. D. McConachie, *Virginia Medical Semi-Monthly*, December 7th.

THE TREATMENT OF PUERPERAL FEVER.[1]

By H. J. BOLDT, M.D.,

NEW YORK.

Under the term puerperal fever we should class only those fevers which are caused by the entrance into the system of the puerperal woman of pathogenic micro-organisms, or toxins, from some part of the genital tract. I would also include fevers caused by similar infection following abortion.

The main varieties of puerperal fever are: Acute bacteræmia; chronic bacteræmia; sapræmia and septic infection (local septic infection); from the latter, however, subdivisions may be made.

That the meaning of the terms used by me may be generally understood, I will give their definitions. The reasons for their introduction, instead of clinging to the old terms septicæmia and pyæmia, and the term septic infection in its broad sense, may be found in an article entitled "Septicæmia and Pyæmia, and the Indications for Abdominal Section and Drainage and the Indications for Hysterectomy in Puerperal Infection."[2]

Acute bacteræmia is a blood disease caused by parasitic micro-organisms invading the circulatory system from some primary seat of infection, the infection-producing elements multiplying so rapidly in the blood that the patient usually succumbs within five days after the beginning of the disease. Generally the parasitic germs are streptococci pyogenes; other pathogenic germs may, however, also be present.

Chronic bacteræmia is likewise caused by the invasion of the system by streptococci pyogenes alone or in conjunction with other pathogenic germs, but they disseminate from an infected thrombus. They are not diffused into the system in one large quantity, neither are they possessed with the same foudroyant virulence from a clinical viewpoint. The production of the abscesses found in this condition, upon which the pathological difference between acute and chronic bacteræmia depends, is due to the parasitic organisms finding a resting-place outside of the blood circulation, and there giving rise to abscess formation.

All these infection diseases being due to "septic infection" in a broad sense, I would limit the application of this term to those cases in which the infection is local. A local infection may be accompanied by severe constitutional symptoms.

Sapræmia is caused by the absorption of decomposition products in the genital tract: toxins, saprophytes; as for example, placenta, decidua, blood, or lochia. This disease may develop into one of those previously spoken of.

In many instances it is impossible to classify the individual case into any one of these varieties until the patient has been under observation for a longer or shorter time. The only term which, in a clinical sense, will cover all varieties is "septic infection." Having but one term for these various forms is unfortunate from a scientific viewpoint, in that this term, as heretofore employed, does not convey a clear understanding of the individual case; it is, therefore, inadequate. For clinical purposes at the bedside, however, I know of no substitute which serves better. Because of the indefiniteness of the term "septic infection," it should never be used in medical writings without such details as will convey the exact condition of the patient.

Acute bacteræmia, as I conceive that illness, is the most serious. According to reliable authors the mortality is ninety-seven to ninety-eight per cent. I myself do not remember having seen a single instance of

[1] Read at the annual meeting of the Medical Society of the State of New York, January 29, 1901.

[2] New York Medical Journal, January 26, 1901.

recovery. In chronic bacteræmia the chances for recovery are somewhat better.

The prognosis in sapræmia depends upon our ability completely to remove the putrefactive factors soon after the occurrence of fever, before other infection may have taken place.

In the treatment, prophylaxis is the most important. It is, therefore, imperative to observe the rules of antisepsis in obstetrics. A physician who is busy with a large general practice, in which contagious or infectious diseases are likely to occur at any time, must be especially careful. It is better that he does not attend confinements at all, because the time at his disposal is insufficient for him to observe that care of his person in bathing and the change of clothing which is required with our present knowledge to avoid conveying infection to the puerperal woman. The greatest, in fact absolutely unpardonable, error that can be committed by a physician is, if he is in attendance on a woman with puerperal fever, to attend another confinement, or to proceed with surgical intervention in abortion cases.

The first rule in the treatment of puerperal fever is to keep the patients at perfect rest; they must be restrained from undergoing even the slightest physical exertion. Next, attention must be directed to the seat of primary entrance of the fever-producing agents. To illustrate: A laceration of the perineum resulted during delivery, and was repaired by the attendant. Two or more days subsequently the patient develops fever. Inspection of the wound shows that the margins are reddened and slightly œdematous. Examination of the abdomen shows the absence of peritoneal irritation. Nor is a cause for the elevation of temperature to be found on examination of the rest of the body. With such patient the sutures should be removed: and if this is done it will be found that no attempt at union has taken place. The surface is probably covered with purulent secretion. If the infection has not gone much beyond the seat of entrance the temperature will be reduced in twenty-four or forty-eight hours, and the patient will have a practically normal convalescence if proper treatment is instituted.

If the seat of infection be about the vulva or in the vagina, or both, which can be ascertained by inspection, the treatment should likewise be directed to cleanliness. The parts should be wiped with absorbent cotton steeped in some antiseptic solution (I prefer a five-per-cent. solveol or an antinosin solution) dried and dusted with one of the so-called antiseptic powders, as xeroform, nosophen, aristol, acetanilid, etc. I have not noticed any difference in the therapeutic effect of either of those named. Iodoform should not be used on account of its odor. Neither should one use a medicament which produces an escharotic effect, because the scab soon becomes loosened from the moisture of the lochia, and then the field beneath becomes a fertile soil for the propagation of cocci and bacteria. Patients in whom the abraded surface is covered only with pus, make a rapid recovery, but those in whom the seat of infection is covered with grayish-white membrane, the so-called diphtheritic endovulvitis and endocolpitis, do not get well so soon, especially if the infection has progressed into the deeper structures, into the lymphatics. Those patients in whom the local lesion is gangrenous must be regarded with seriousness. But how much proper care will do even in serious conditions is illustrated in the following instance which has come quite recently under my observation: A woman had sustained an extensive complete perineal tear by forceps delivery. When seen in consultation two days subsequently, the temperature was 103 F. in the axilla. The labia and vulva were much swollen and extensive gangrene was present. In her home, where the necessary care could not have been had, she would probably have died, whereas in the hospital she recovered in a few weeks.

If no area of infection is found about the entrance of the genital tract, it is advisable to place the patient on the edge of the bed, or still better on a table, and carefully to inspect the vaginal mucous membrane and the vaginal portion of the cervix, the latter frequently being the seat of infection. Much care should be exercised when this inspection is made not to reopen small wounds and thus to cause a new seat for infection. Small vaginal retractors are best adapted for this purpose. If no local injury is found to account for the existing symptoms, then the interior of the uterus may be examined if the condition of the patient seems to demand it. It should not be done, however, if the general condition of the patient, especially the pulse, is good, and the temperature is not above 101° or 102°, because retained placental tissue or decidua is usually expelled spontaneously in a short time. Therefore, unless we know that such foreign elements are within the uterus, we should not explore its interior unless the condition of the patient seems to make it necessary. It is, in short, best to abstain from unnecessary meddling with the genital tract.

When the seat of infection is in the uterus, this organ is found enlarged and relaxed, and the cervical canal generally admits of the introduction of the index finger.

When the fever depends on retained products of conception, blood clots, or retained lochia (lochiametra), the treatment becomes clear, if the patient's condition does not soon improve from spontaneous expulsion of the fever-producing factors. Under antiseptic precautions in every detail the uterus must be cleansed of all foreign material. If only blood clots or retained lochia are present, an intra-uterine douche with some mild antiseptic solution suffices. If decidua or placental tissue is present, it should be removed. I would advise discarding the curette for this purpose unless the physician is fully familiar with its use in such cases, because of the great danger of perforating a puerperal uterus; besides, one can judge better by touch with his finger than with an instrument. I am especially opposed to curetting in instances of septic endometritis, never having seen an instance in which I believed that this procedure was beneficial; but, on the contrary, I have seen much harm result from it.

An intra-uterine douche before and after manipulations within the uterus is always advisable. It is best to have the fluid flowing slightly while we are inserting the irrigating tube into the uterus, thus making sure that the fluid is not too cold or too hot, and also because air is thereby prevented from entering the uterus.

The best manner to introduce the irrigating-tube is to hold it between the index and middle finger; then the point is introduced into the cervical opening. With the other hand the body of the uterus is pressed slightly backward during the introduction of the tube into the uterus, so as to straighten the cervico-uterine canal, the body of the uterus usually being sharply anteflexed after confinement. The irrigator should be held but little above the plane of the pelvis, so that the pressure of the irrigating fluid is not too great.

Should the patient complain of colicky pain while the irrigation is in progress, it is an indication that the uterus is too much distended by the fluid, and the irrigator should be lowered so as to allow the fluid to escape without more flowing in. It is best to use a glass irrigator, so that should the return fluid contaminate the irrigating fluid, the latter must be renewed. It is good practice to keep the external hand on the uterus and make slight friction to induce uterine contractions while the irrigation is in progress.

Whether the irrigation should be repeated depends

on circumstances, and is a matter of opinion; generally one douche, properly given, is sufficient. If the foreign material has been completely removed, and if there is no septic infection associated, the temperature falls to normal, or nearly so, in a short time after the douche has been given.

The condition which in my opinion indicates repetition of the intra-uterine irrigation, is when the secretions from the uterus are purulent and when there is a continuation of fever. Under such conditions I have seen benefit from repetition of the douches with a twenty-five to seventy-five per cent. solution of peroxide of hydrogen; or, if that is not at hand, some other antiseptic solution; stronger bichloride of mercury than 1 : 10,000 excepted.

Intra-uterine irrigations are of mooted therapeutic value with the medical profession as a whole. When one looks through the literature on this subject, it will be found that there is as much weighty argument against as in favor of them. My opinion is that intra-uterine washing, except under the circumstances alluded to, is useless. I believe with Chazon[1] that patients who recover when they are systematically used get well, not because of them, but despite of them.

The reason for advocating douches, as mentioned, is not for their effect on the deeper structures, but only to rinse off infection elements which may be located superficially.

I have found that if no intense systemic infection were present, and if the uterus remained enlarged and relaxed after being cleansed of decidua or placental tissue, a method of treatment which has been of apparent benefit is gentle massage of the organ at intervals varying from one to three hours. The massage is given in the same manner as when used for the purpose of inciting uterine contractions for expulsion of the placenta; namely, a small circular motion.

Let us now consider septic infection, according to the limitation set down in my definition.

I have seen no benefit from placing gauze in the uterus for the sole purpose of draining off secretions; and as for curetting of the uterus, that treatment has been misused more than any other. To this fact I called attention years ago, and now take opportunity to reiterate my opinion. It is an especially dangerous procedure in a puerperal uterus—even in the hands of proficient operators occasionally perforations of the soft puerperal uterus have been caused by a curette. I would limit this operation in puerperal uteri to those of large experience in the use of a curette, and even then it should be made use of only if retained placental tissue or decidua has been located by the finger and cannot be removed by it. For septic endometritis curetting should never be done, because its effect is to intensify the infection by causing fresh wounds.

Vaporization is more effective on infection elements in the deeper structures of the uterus, and, according to Snegirjow[2] who is the originator of this method of treatment (which, however, was brought more into prominence through the writings of L. Pincus, of Dantsic, than any one else), is the treatment par excellence in septic infection of the uterus. The antiseptic and hæmostatic properties of steam are well known, but we must not lose sight of its dangers—when applied to the interior of the uterus it causes deep destruction of the uterine tissues when used sufficiently long to produce innocuousness of pathogenic germs situated in the muscular structure of the organ; in this country this treatment has not been so favorably accepted as elsewhere.

[1] "Die Streitpunkte in der Puerperalfieberfrage;" Volkmann's Hefte, No. xii., Neue Folge.

[2] Berliner Klinik. Sammlung klinischer Vorträge, 1895, No. 82.

If the infection has localized itself in the pelvic cellular tissue or the pelvic peritoneum, the application of an ice coil or ice bags should be resorted to. In such conditions the inunction of metallic silver ointment (unguentum Credé) is also beneficial; it has given me better results than the use of mercurial ointment. As soon as there is evidence that pus has formed, opening of the abscess should be resorted to, provided there is positive evidence of the pus accumulation conveyed to the examining finger; the incision should be large so as to permit thorough cleaning and drainage.

Credé[1] speaks highly of soluble metallic silver (argentum colloidale) as a continuously acting antiseptic. He uses two or three pellets wrapped in gauze, and introduces them up to the fundus, the distal strip of gauze protruding from the external opening. The vagina is then loosely packed with gauze which is changed daily. The intra-uterine gauze should remain for five days. Credé takes the right view of how the remedy should act to be of benefit: its action must not be only local, but its antiseptic properties, its destructive action on the sepsis-producing organisms, must be conveyed through the circulation. This property he claims for the soluble metallic silver.

Pyosalpinx diagnosed during the puerperium is also frequently of gonorrhœal origin, the latent inflammation in the tube being lit anew through an infection in the puerperal state. Gonococci may be found quite frequently in post-puerperal pelvic exudates, but we know that a gonorrhœal pelveoperitonitis is not likely to endanger life. Experience has taught me that the safest plan of treatment in such cases is by vaginal incision; the operation should, however, not be done rudely; in preparing a patient for it she must be moved gently, so that adhesions in the pelvis are not disturbed.

With patients ill with septic infection who are not benefited by the methods of treatment spoken of, or when we have reason to believe that additional resort to minor interventions would be useless, and who are gradually getting worse, the most heroic measure comes up for consideration; namely, to remove the source of infection entirely—to do a hysterectomy, if the continuance of the infection comes from the uterus alone.[2] Serum treatment may be of benefit in some such cases, but I have been unable to convince myself of it.

There are patients ill with general septic peritonitis of a moderately virulent form, so far as the intensity of the infection goes (diplostreptococcus infection?), who may occasionally be saved by timely surgical intervention. An illustration of an instance in which operation was delayed will best serve my purpose:

Mrs. O—— underwent a difficult delivery, during which the forceps was applied unsuccessfully several times; subsequently craniotomy was performed, there being a generally contracted pelvis. She was seen by me four days after delivery. An exudate was felt in the pelvis, and another in the right lower abdomen, besides there was evidence of peritonitis, but not of the foudroyant type. Both abscesses were opened by free incisions and drained of a large quantity of seropurulent fluid. Some days subsequently another intraperitoneal exudate was opened per abdomen on the opposite side. After each surgical intervention the patient improved, but soon relapsed again. There were chills and hectic fever, the temperature ranging between 101° and 104° F.; diarrhœa; in short, there was the typical picture of a diffuse septic peritonitis. The most careful examination failed to reveal other sacculated accumulations until during the fourth week of her illness, when it was evident that there was another accumulation beneath the liver. This last ex-

[1] Monatsch. f. Geburtsh. und Gynäk., No. 8, p. 585.

[2] See New York Medical Journal, January 26th.

amination was made in the evening, and I had intended to operate early on the following day. During the night she had an attack of vomiting, followed by collapse, from which she did not rally. The autopsy showed the changes characteristic of diffuse septic peritonitis of long standing. Numerous pockets between the intestines were filled with purulent fluid; one larger was beneath the liver, another beneath and behind the stomach; the latter had ruptured during vomiting and caused the direct fatal issue. In this instance, had I not hesitated at a major operation in the beginning, after evacuating the discernible septic collections, but had performed an extensive abdominal section, separating the adhesions as much as possible, with free flushing of the peritoneal cavity with saline solution, and then used drainage, she would have had a chance to get well.

Such instances of septic peritonitis have been observed several times by me. But we must not forget the fact, and hence our hesitation to operate, that such patients sometimes get well without any operation, by the observance of strict rules in diet, perfect rest, appropriate stimulation, the application of an ice coil to the abdomen, and silver or mercurial ointment inunctions. The importance of rest for such patients is well illustrated in the instance cited. By it the adhesions surrounding an exudate become firmer. The rest should not be confined to bodily quietude alone, but also to intra-peritoneal rest. To obtain this the patients should get such food as will not cause hard fecal accumulations; the food must be of such character that it is easily assimilated, as peptonoids, butter, eggs, beef tea, and strained farinaceous food stuffs. Milk should be avoided, unless it is first peptonized, and even then it should be given sparingly. Among stimulants, Tokay wine, whiskey, or brandy largely diluted with cold water in small quantities should be given, unless the condition of the kidneys forbids their use. Occasionally opiates are serviceable.

For acute bacteræmia I have nothing to suggest. All patients seen by me have died, no matter what method of treatment was adopted. The cases reported as cured from this form of disease, by some method of local treatment or by some opertation, were undoubtedly errors in diagnosis; such patients had, in my opinion, a septic infection with severe constitutional symptoms.

Eberhart[1] recommends infusion of a 0.9-per-cent.-saline solution. In my hands this treatment has likewise been unsatisfactory. The usefulness of an anti-streptococcus serum, as now in use, I consider a delusion in this disease, although I believe that we may look in the direction of a serum treatment to avert death in such patients.

Opening of the cul-de-sac of Douglas and drainage with gauze on the first appearance of infection symptoms, with a view of aborting acute bacteræmia, provided the infection source is not to be found on inspection of so much of the genital tract as can be seen by the eye, and provided that the infection is not attributable to decomposing foreign elements within the uterus, is a method practised by some of my colleagues. I have also performed this operation, but have given it up again. I cannot understand how an incision into the pelvis with gauze placed into it, can drain off micro-organisms in the blood; and what is the use of draining when there is nothing to drain?

Chronic bacteræmia must be treated according to the indications in an individual patient. Metastases, if within reach, should be incised. If we should be able to diagnose metrophlebitis, and have reason to believe that the thrombosis is still so limited that it can be removed by hysterectomy, this operation may be done.

AN OPERATION FOR THE RELIEF OF STOPPAGE OF THE TEAR PASSAGE, ABSCESS OF THE SAC, ETC.

By ERASMUS A. POND, M.D.,

BANGOR, ME.

The object of this operation is to establish a permanent opening into the nose, and to give in this way free drainage of the lacrymal sac, thus relieving epiphora and obviating any danger of an abscess, in one operation. I have found probing to be unsatisfactory both to the patient and to myself.

The operation is very simple. A long silver probe with one end blunt and the other end having an eyelet

Case I.

large enough to carry a coarse silk string, is threaded and passed through the canal into the nose, where the end is seized with a pair of forceps and drawn out through the nostril. The probe is then unthreaded and the string is left in this position with the ends

Case II.

tied together. The string is worn about one week, being drawn through the nose two or three times a day. I usually, in tying, make quite a large knot, and when this is pulled through the canal it makes a good large opening. I have used this operation for the past

Case III.

two years with gratifying success. The canaliculus may be slit or not, according to the judgment of the

operator. I have done most of these operations under cocaine, but in some cases have used ether. There is no pain after the first operation, and the string may be turned without causing any hurt. In abscess of the sac the string will give good drainage and so save the necessity of an opening on the cheek. I report three severe cases of long duration which were entirely relieved and remain so after a period of two years. There are many other cases equally successful.

Case I.—I. D——, aged forty-six years, has been bothered with the tears flowing on to the cheek and recurrent abscesses of the sac for ten years. During this time he has frequently had probes passed but without any permanent relief. The eye and nose were cocainized and the string was placed in position. He wore the string ten days, turning it two or three times a day. The result was good.

Case II.—Mrs. W. M——, aged twenty-six years, had stoppage of the tear passage and abscess of the sac. The string was passed under cocaine and worn ten days. The result was good.

Case III.—Mrs. H——, aged fifty years, has had stoppage of the tear passage for many years and had received no benefit from repeated probing. The string was placed in position under cocaine and worn one week. The result was good.

As the string causes no solution of continuity in the mucous membrane there can be no stricture, as is the case in all other operations, hence the opening remains permanent. Another advantage of this operation is the doing away with repeated probing, as this is all done in one operation.

Clinical Department.

THE MALARIAL MOSQUITO ON THE SUSQUEHANNA.

By HARVEY B. BASHORE, M.D.,

WEST FAIRVIEW, PA.

During the past summer I made some observations to ascertain the prevalence of the malarial mosquito (Anopheles) in this locality; namely, the suburb of Harrisburg. The conditions existing this season were, according to the popular notion, very favorable for malarial development—a low stagnant river and considerable hot weather.

The recognition of the Anopheles is extremely easy with the aid of a small pocket lens; the characteristic points being the spotted wings, long "feelers," and resting-position. This resting-position, although rarely at right angles to the surface, is at such an angle that with a little practice one is able to tell Anopheles from the position alone. Mr. L. O. Howard, the government entomologist, kindly verified the species for me. During the great heat wave from August 14th to August 22d inclusive, while the temperature was ranging between 70° and 100° F., mosquitos were exceedingly plentiful and became a decided annoyance, even in the houses which were properly screened. During this period I captured and examined five hundred and forty specimens, of which four hundred were Culex and only one hundred and forty Anopheles (one hundred and thirty-three being quadrimaculatus and seven punctipennis); that is, only twenty-five per cent. were malarial. During this time there was very little malarial fever; I saw, I believe, only one case of intermittent fever in my own practice.

After the great storm in September, a cool wave spread over the region with the temperature in the morning ranging between 50° and 60° F. During this period, although mosquitos seemed very rare, I managed to capture seventy-eight, of which fifty-six were malarial—about seventy-four per cent. Then (hardly a mere coincidence) there was an unusual outbreak of intermittent fever; personally I saw twenty cases in ten days, mostly tertian, requiring large doses of quinine and showing a marked tendency to relapse later on.

Late in September and at the beginning of October the Anopheles occurred only in the ratio of fifty per cent., and during this time there was a diminution of the number of cases of fever—twelve in thirty days.

In the month of October we had several severe frosts, and in the latter part of the month very fine weather, but Anopheles seemed to have gone into winter quarters, for only sixteen per cent. of the mosquitos belonged to that family; likewise the intermittent fever seemed to have vanished, for there existed hardly a case. In every instance the mosquitos were captured in the same place—the back porch and an outbuilding of my own residence—and, although there was no fever in this house, nearly all my cases occurred within a few blocks of it.

PLACENTA PRÆVIA OR DETACHED PLACENTA.

By GEORGE W. SQUIRES, M.D.,

EAST AVON, N. Y.

Mrs. T. Mc——, aged twenty-one years, was taken in pain about 8 P.M., December 10, 1899, with what she informed her husband must be labor, although gestation was only at the eighth month. There coming quite a sharp hemorrhage, they were frightened and called me hurriedly. I arrived in half an hour, found the patient very much excited and complaining of pains low down in the pelvis. As soon as I could clean my hands I made an examination and was sightly disturbed to find a soft mass in the lower segment of the uterus. On sweeping my finger around the body it seemed to be almost entirely detached from the uterine walls, excepting a slight adhesion on the right side. Before I had decided as to my procedures there came a sharp, long pain, when the afterbirth popped out of the uterus and vagina into the bed. I hastily examined to see what we had, and the placenta had been delivered with the cord attached. Expecting hemorrhage, I examined and found the breech presenting, the uterus closely hugging the child with not a bit of bleeding. During slight uterine relaxations I pulled down a foot, but made no traction, rather delaying delivery by encouraging the mother not to strain, so that we procrastinated the delivery for two hours. The child, we were satisfied, was dead, and had been for some days. So having no anxiety for the viability of the child, all attention was for the mother. As long as the uterus grasped the child and there was no concealed or outward bleeding, I waited for Nature and watched to see what she would do. The uterus was not in tetanic rigidity, as there was rhythmical relaxation. The child moved down, but only as the uterine cavity lessened by contraction. Slowly and wisely Nature managed the situation, and with the child slowly extruded, the uterus shut down in permanent contraction, the bleeding having been less than in many a normal labor. The woman made a natural and rapid convalescence.

To Prescribe in the Metric System.—All that it is necessary for the physician to learn is that 1,000 milligrams make one gram; 1,000 grams or cubic centimetres make one kilo or litre; 65 milligrams make one grain; 15½ grains make one gram; 31 grams make one ounce.—American Association for Advancement of Science.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM WOOD & CO., 51 Fifth Avenue.

New York, February 2, 1901.

WHAT SHOULD BE THE LEGAL REQUIREMENTS OF A PRACTITIONER?

WE have repeatedly called attention in the MEDICAL RECORD (February 10 and September 29, 1900) to the need of some revision of legislation bearing upon the practice of medicine, and we have hoped that the matter could be placed before the proper committee in such a way that the present discrimination against the licensed practitioner could be removed.

A bill has been presented to the legislature of this State, which, if passed, will place the osteopath and the Christian Scientist *et id genus omne* in the position of being compelled to pass the State examination in order to practise their peculiar forms of pseudo-therapeutics without interference by the authorities. The proposed act is in the form of an amendment to an existing law, and its important section reads as follows: "Any person shall be regarded as practising medicine within the meaning of this act, who shall prescribe, direct, recommend, or advise, for the use of any other person, any remedy or agent whatsoever, whether with or without the use of any medicine, drug, instrument or other appliance, for the treatment, relief or cure of any wound, fracture, or bodily injury, infirmity, physical, or mental or other defect or disease." We should prefer to have the amendment read: "Any remedy, agent, or method whatsoever," and, if thus altered, we do not see how the act could be circumvented by the unlicensed charlatan, or how it could reasonably be objected to by any legislator.

At least one decision has been given in this State (Smith *vs.* Lane) that to practise osteopathy is not to practise medicine, and we have attempted to show the unfairness of this point of view (MEDICAL RECORD, September 29, 1900).

The reasons which led to this decision would also show that to practise Christian Science, or any -pathy or -ology is not to practise medicine, and we think that one argument advanced in favor of this decision has been that no drugs were ordered by the various unlicensed individuals. It is absolutely incomprehensible to us that even the most ordinary lay mind should not at once perceive that the mere ordering or using of a drug is not practising medicine, and that the practising of medicine consists in assuming responsibility, making a diagnosis, and suggesting treatment, be that treatment medicinal, mechanical, or psychical in its nature.

Now, the unlicensed practitioner undoubtedly does all of these latter things, especially when he is an "osteopath" or a "Christian Scientist," and is in consequence just as certainly practising medicine as is the registered physician who straps a sprained ankle, or applies counter-irritation, for instance, though in the case of the former there is no legal responsibility, while the registered physician can be mulcted in damages for any real or apparent dereliction, or lack of skill. This question of legal responsibility is one of great importance, and if it can be properly presented to the committee of the legislature, its decision ought to prove of value to the medical profession. We can make it clearer perhaps by an illustration. A man sustains a Pott's fracture and, consulting a regularly licensed practitioner, is told that he has a sprain of the ankle and is treated accordingly. Two months later he has the characteristic deformity and disability, and, the facts being proved, any jury would award him damages, because the medical man had not used due care. In this instance, the State's license to practise is in a measure a guarantee that the holder of the license is capable, and the possessor of knowledge up to a certain standard, and that the State will hold him responsible if he does not use due care, knowledge, and skill in the treatment of those who apply to him for advice.

In the case of the unlicensed practitioner, the patient is just as well off, as far as recovering damages is concerned in the event of disability or deformity after such an injury as we have described, as if he had asked advice and treatment from the first stranger whom he met after he was injured. No jury would award damages, and there would be no legal redress, because the practitioner is not recognized by law, and the patient has solicited treatment knowing the conditions. This aspect of the case certainly ought to appeal to the public. The medical profession simply demands that every individual who assumes the responsibility of caring for the sick and injured shall pass the State examination, and shall take out a license, so that, no matter what ideas he may have with regard to therapeutics, he shall at least satisfy a duly constituted board that he has a good knowledge of the fundamental branches—anatomy, physiology, obstetrics, and pathology. With these conditions fulfilled, the system of therapeutics is not very important.

All members of the profession in this State, who are interested in this matter, and who wish the "osteopath" and "Christian Scientist" to be prevented from practising without a license, should write at once to their assemblymen and State senators asking their support for "Assembly Bill, printed No. 167, Introductory No. 167," which is the title of the amendment.

MYELOPATHIC ALBUMOSURIA.

IT is well known that serum-albumin is not the only, withal it is the most important, proteid in the urine. There occur, besides, serum-globulin, albumoses or peptones, hæmoglobin, nucleo-albumin, fibron, and

histon. The serum-globulin is invariably found in association with serum-albumin. Albumose and peptone have been present under various conditions, although a special variety of albumose has been described as occurring particularly in association with a certain disease of the bones, to which the designation multiple myelomata has been given, but T. R. Bradshaw (*British Medical Journal*, November 3, 1900, p. 1304) prefers to describe the condition as myelopathic albumosuria. Only a small number of cases of this disorder have been recorded in the literature, although it is possible that the condition often escapes observation, and at times it may be mistaken for other diseases. In most cases the cancellous tissue of the bones of the trunk is involved by a cellular growth, with disappearance of the osseous tissue and the presence of large amounts of albumose in the urine, which becomes turbid when heated, clear again when further heated, and once more turbid on cooling. Hydrochloric and nitric acids cause a precipitate that can be dissipated by heat, but recurs on cooling. The substance is precipitable also by alcohol, although soluble in water. The albumose has a tendency to separate out spontaneously on standing; such separation may take place in the kidneys and the bladder, and the urine may in consequence present a turbid appearance when voided. In some of the bones, chiefly the ribs, the sternum, and the bodies of the vertebræ, the hard substance may be reduced to a mere shell, which breaks on the slightest pressure with the fingers, while the cancellous tissue has almost entirely disappeared. Spontaneous fractures of ribs are common. The interior of the bone is occupied by a reddish, gelatinous, greasy mass, somewhat like spleen pulp, which can readily be expressed from the thin and brittle bones. Microscopically this consists of round and spindle-shaped cells, and it resembles sarcoma.

The disease in question occurs in the second half of life, and apparently with greater frequency in men than in women. Generally there is first complaint of pain in the lumbar region, increased by movement. In addition, the appearance is anæmic. The pain varies in severity, but gradually becomes more marked and more widespread, invading gradually the loins, the ribs, and the sternum, the latter of which become the seat of tender spots and lose their rigidity. The bones may yield to pressure or undergo fracture spontaneously or on slight provocation. Curvature of the spinal column results, with loss of mobility. The bones of the extremities usually escape, so that the patient continues to go about in spite of pain, weakness, and deformity.

The disease appears to be invariably fatal, although at times its course may be greatly protracted. Remarkable intermissions occur frequently, and may give rise to false hope of improvement. Death results from exhaustion or intercurrent disease, especially pneumonia. Only symptomatic treatment is indicated. The pathogenesis of the disorder is obscure, although the frequent association of albumosuria with disease of the bone marrow is suggestive of a possible relation between the two.

That multiple myelomata is not the only disease of the bone marrow with which albumosuria is associated is shown by a case of lymphatic leukæmia recently reported by Askanazy (*Deutsches Archiv für klin. Med.*, Bd. lxviii., Hft. 1 and 2, p. 54), in which that condition was present. A second case of lymphatic leukæmia was, however, unassociated with albumosuria.

NEED OF ENDOWMENT FOR SCIENTIFIC RESEARCH AND TEACHING.

No medical man will be found bold enough to controvert the assertion that the greatest aid to the advancement of science and to the propagation of a more general knowledge than now obtains among the medical profession of bacteriological research would be the establishment of properly equipped laboratories in connection with all the large hospitals of this country. The chief reason why scientific men of America have lagged behind in original research work has been the want of opportunity of pursuing the same as compared with men of the European continent. Dr. St. John Roosa gave voice to this need a short time ago, and now Sir Michael Foster, in the January issue of the *Nineteenth Century*, utters an almost identical complaint as regards the shortcomings of the large hospitals of London in this respect. Sir Michael Foster says: "The phenomena of disease being phenomena of living beings present themselves, in most if not in all cases, as problems, as mixed problems of physics, chemistry, and biology, to be grappled with by the doctor as they are grappled with by the physicist, the chemist, and the biologist. The analysis to be adequate must be carried out by means of adequate appliances. The days when a test tube, a spirit lamp, and an imperfect microscope supplied all the equipment needed for such an analysis have long passed away. Such an examination as the present state of science makes imperative can no longer be conducted in a corner behind a screen. It is to-day absolutely necessary that for the carrying out of the exact and complete analysis of the phenomena of disease, demanded alike in the interests of the individual and for the well-being of mankind, each hospital should be provided with laboratories, clinical laboratories fully equipped with all the needed appliances of science. And the complaint which I am now making narrows itself down to this, that in spite of all which has recently been done, our great hospitals in London are still very deficient in such an equipment. I venture to assert that in this respect our London hospitals in general are both absolutely behindhand and relatively in the rear of hospitals, not only in other countries but even in our own provinces. During a recent stay in the United States and in Canada I was told, not once only but again and again, that in the experiences of their medical graduates visiting London, while our ordinary medical teaching—the teaching up to graduation—is unsurpassed in excellence, our general hospitals are of little use to the graduate, and that the special hospitals do not supply him with what he needs." The real use of a post-graduate course is not, as many seem

to imagine, to learn what should have been learned before graduation, or even to polish and place the coping-stone on the edifice of medical knowledge, but, as Sir Michael Foster truly says: "The post-graduate study, which alone calls for strenuous support, is that study which fits the student for the task of inquiring after new truth, of grappling not with the known but the unknown." Until that time arrives when America either by private generosity or by the help of the State shall have established laboratories commensurate with the size and wealth of the country, will she be in a position to compete on equal terms with the men of science of Europe. That such a time is advancing with rapid steps we feel assured, and also look forward to the result with complete confidence.

INTRA-SPINAL COCAINIZATION.

The Lancet, in its annual retrospect of affairs medical and surgical, refers to the above subject as follows: "Among the year's events in this department of medical science may be placed first in order, but rather on account of their novel development than of their intrinsic merit, the introduction of spinal cocainization as a definite mode of producing analgesia, and the extension of local anæsthesia by interstitial infiltration. To Leonard Corning, an American physician, must be accorded the initiation of the suggestion (1885) that an extended anæsthesia would follow the injection of local anæsthetic bodies into the sheaths of nerves or of the spinal cord itself." It is gratifying to find that the well-known London medical journal recognizes the fact that Dr. Corning was the first to introduce the method of local anæsthesia into the spinal region, and gives honor where honor is due. Many European medical papers claimed the credit for Tuffier, and more or less ignored the existence of Corning. Some journals on this side also did not appear to be aware that one of their own countrymen was the first to try this mode of using a local anæsthetic. Although it must be admitted that up to the present cocainization of the spinal cord has in no wide sense replaced general anæsthesia and has its own limits of application, yet it is more than probable that by no means the last word has been said on the matter. Under certain circumstances its benefits may be in time fully demonstrated.

University for Women in Tokio.—The *British Medical Journal* is responsible for the statement that in go-ahead Japan the decision has been reached to erect a university for women. This institution will be established in Tokio, and it is hoped will be opened in the early spring of this year. That Japan intends to strive its utmost to keep in the vanguard of civilization seems evident, and the founding of a university for women is but another illustration of this fact. Japanese young women are, it is said, eager to avail themselves of higher education not only in the knowledge of medicine, but also in the Polytechnic School, an institution for the training of civil engineers.

News of the Week.

Glanders in Essex County.—The board of health of Monclair, N. J., says *The Sun*, has become alarmed at the prevalence of glanders in the county, and has decided to present a memorial to the State board of health, and to the district assemblyman, requesting that the legislature be asked to grant a special appropriation of $15,000 to be used in guarding against an epidemic and stamping out the disease.

Dr. Hiram N. Vineberg has been appointed adjunct attending gynæcologist to the Mount Sinai Hospital in this city.

The Omega Upsilon Phi Fraternity (medical) has just organized two new chapters, one at the University of Colorado, composed of fifteen students and several members of the faculty; the other, a graduate chapter in New York City, to be known as the "Henry C. Coe Chapter," in honor of Professor Coe of the University and Bellevue Hospital Medical College.

Navy Department, Bureau of Medicine aud Surgery, Washington, D. C.—Changes in the medical corps of the navy for week ending January 26, 1901. Assistant Surgeon C. N. Fiske detached from the *Wheeling* and ordered to the *Mohican* when the former is put out of commission. Assistant Surgeon H. O. Shiffert appointed assistant surgeon from December 26, 1900. Medical Inspector D. N. Bertolette detached from the medical examining-board, Washington, and ordered home January 31st. Surgeon A. C. H. Russell ordered to Washington for duty as a member of the medical examining-board, January 31st. Surgeon W. H. Rush ordered to the Pensacola naval station for recruiting and other duty. Passed Assistant Surgeon R. K. Smith detached from the *Pensacola* February 2d, and ordered to the *Wisconsin* February 4th. Assistant Surgeon M. V. Stone detached from the *Solace* and ordered to the *Isla de Luzon*. Assistant Surgeon H. H. Hass detached from the *Isla de Luzon* and ordered to the *Solace*.

A Medical Marriage Bill has been introduced into the Wisconsin legislature which provides that no persons can marry who are suffering from insanity in any form, from drug addiction, tuberculosis, syphilis, or any of various other constitutional diseases named in the bill. Every person who wishes to marry is required to go before an examining-board of three surgeons, to be appointed in each county of the State by the county judge, and must pass an examination before a marriage license can be issued to him or her. In addition, all male candidates for matrimony who are under twenty-five years of age and all female candidates under eighteen years must produce a written consent of their parents before they can secure a license. Any clergyman, justice of the peace, or other person who can perform marriages and who marries any couples who do not produce a certificate from the examining physicians of his county is to be fined not more than $500 or confined in prison not more than one year.

Pekin Invites Pestilence.—A report from Pekin, dated November 15th, says: "Sanitary conditions here are becoming serious. Since the foreign occupation many Chinese have died of smallpox and other infectious diseases. Fearing that their funerals would be interfered with, they have kept most of the coffins containing their dead in their houses and courtyards. The question of removing garbage has become one of grave importance. As the natives are forbidden to deposit refuse in the streets, there is now an enormous accumulation in their dwellings and yards, which threatens a serious epidemic. In view of the large number of troops in and near the capital, the consequences of such an outbreak would be frightful. Smallpox, which is always prevalent, is much more malignant during winter, and the danger here is now alarmingly increased."—*Sanitarian.*

The Queen's Last Illness.—The following account of the gradual failure in the health of the Queen, which is believed to have been written by her Majesty's physicians, is published in the *British Medical Journal* of January 26th: "The Queen's health had been failing for the past twelve months. The symptoms were mainly of a dyspeptic kind and were accompanied by impaired general nutrition and periods of insomnia and later by occasional slight and transitory attacks of aphasia, the latter suggesting that the cerebral vessels had become damaged, although her Majesty's general arterial system showed remarkably few signs of her age and constant brain work through her long life of royal responsibilities and imperial events. The domestic sorrows and anxieties which crowded into her late years may undoubtedly be held in some measure to account for this discrepancy between cerebral and general vessel nutrition. The thoracic and abdominal organs showed no signs of disease. Dyspepsia, which tended to lower her Majesty's original robust constitution, was especially marked during her last visit to Balmoral. It was there that the Queen first manifested distinct symptoms of brain fatigue and lost notably in weight. These symptoms continued at Windsor, where, in November and December, 1900, slight aphasic symptoms were first observed. They were always of an ephemeral kind and were not attended by any motor paralysis. Although it was judged best to continue the negotiations for her Majesty's proposed visit to the continent this spring, it was distinctly recognized by the physicians and those in closest personal attendance upon her that these arrangements were purely provisional, it being particularly desired not to discourage her Majesty in regard to her health by suggesting doubts as to the feasibility of her trip abroad, to which she had been looking forward. The Queen suffered unusual fatigue on her journey to Osborne on December 18th, showing symptoms of nervous agitation and restlessness which lasted for two days. Her Majesty afterward improved for a time both in appetite and nerve tone in response to the more complete quietude than she had previously consented to observe. A few days before the final illness, transient but recurring symptoms of apathy and torpor with aphasic indications and increasing feebleness gave great uneasiness to her physicians. On January 16th the Queen showed for the first time some symptoms of mental confusion. By an effort of the will, however, her Majesty would for a time, as it were, command her brain to work, and the visitor of a few minutes would fail to observe signs of cerebral exhaustion. On Thursday of last week the mental confusion was more marked, with considerable drowsiness, and a slight flattening was observed on the right side of the face. From this time on aphasia and facial paresis, although incomplete, were permanent. On Friday the Queen was a little brighter. On Saturday evening there were a relapse and graver symptoms, which, with remissions, continued until the end. It is important to note that, notwithstanding the great bodily weakness and cerebral exhaustion, the heart's action was steadily maintained to the last, the pulse at times evincing increased tension, but always regular and normal. Frequently the temperature was normal. Throughout the last few hours of life paresis of the pulmonary nerves set in, but the heart beat steadily to the end. Beyond the slight right facial flattening there was never any motor paralysis. Except for the occasional lapses, the mind cannot be said to have been clouded, and within a few minutes of her death the Queen recognized several members of her family."

State Board of Charities and Governor Odell.—On Wednesday, January 23d, there was a meeting at the Charities' Building of many of the most prominent members of the State board of charities, to consider the bill now pending at Albany to abolish the said board, and to substitute in its stead a single commission with two men as associates, who are to be charged with other duties also. The meeting, after listening to speeches from Mr. Canfield, Dr. Felix Adler, Father McMahon, and others, passed resolutions condemning the proposed changes, and appointed a committee of twenty to take such steps as might be necessary to oppose its passage by the legislature. It is argued by the opponents of the proposed bill that such a measure would be a retrograde movement and against the best interests of those directly concerned. The *New York Evening Post*, January 24th, thus comments editorially on the matter: "If the object of the governor and the legislature in abolishing the State board of charities, and putting three politicians in their place (for they will be such eventually, if not now) is to save money, that object will not be attained, unless their proper work remains undone. If the work of inspection is to be performed at all, it must be paid for."

Smallpox News.—Two cases of smallpox were discovered in Syracuse last week, one of which was in a milk peddler. The health officers will probably quarantine the milk association which furnishes a large part of the milk supply of the city. In Utica also two persons have been stricken with the disease, one of them being a street-car conductor. The health authorities have taken all possible precautions to prevent the spread of the disease. The first genuine case of smallpox in Bellevue was diagnosed as such on Thursday, January 24th. The patient was received the Wednesday previous and supposed to be suffering from

grippe. On Saturday he was found to have smallpox, and was removed to North Brothers' Island. Although there are still some sporadic cases of smallpox occurring in New York City, it may be confidently asserted that there is no fear of an outbreak on a large scale, thanks principally to the energetic measures taken by the board of health. President Murphy has appointed fifty deputy sanitary inspectors to assist in the work of vaccination in the city.

A Grateful Patient's Gift.—According to one of the surgeons of the University and Bellevue Hospital Medical School, says the *New York Tribune*, an *x*-ray machine to cost $1,500 is to be given to the school by a woman who was a patient of one of the members of the faculty, and wished to do something to show her appreciation of his services.

Christian Science Again.—Drs. N. B. Van Etten, John Cabot, and Isaac M. Heller, of Tremont, declare that they will report to the authorities the case of Mrs. Frank L. Hopper, of No. 2085 Ryer Avenue in the Bronx, who died of blood poisoning last week, they say, after they had attended her and had been supplanted by a Christian Science "healer."

Lancet for 1901.—The *London Lancet* has celebrated the opening of the new century by a slight alteration in its compilation. The subjects of the leading articles of that journal are now plainly printed at the head of each article. This innovation, although a not very radical one, will doubtless be appreciated by its numerous readers.

Charges against a Buffalo Hospital.—Formal charges of incompetency, brutality, negligence, and imperfect diagnosis of injuries have been preferred against the house staff of the Fitch Accident Hospital, and are now being investigated by the board of consulting and attending physicians and the hospital committee of the Charity Organization Society.—*New York Evening Post.*

Lunacy Commission.—Since the establishment of the State lunacy commission, the law has required that its president and medical member should be a physician of ten years' standing, and that he should have had five years' actual experience in the care and treatment of the insane, and also should have had experience in the management of institutions for the insane. Senator Brackett and Assemblyman Fish have introduced a bill supported by Governor Odell, striking out all such requirements, except that said member be a physician of ten years' standing. The successor of Dr. Peter M. Wise, who was removed from office by Governor Roosevelt, will not be named until this law has been passed.

Queen Victoria's Medical Attendants in Her Last Illness.—Sir James Reid had been the resident physician of Queen Victoria for more than twenty years. He is a Scotchman, from the neighborhood of Aberdeen, fifty years of age, and comes of a medical family. He was selected, it is said, for the position he held so long by the late Sir William Jenner, who was, until his death, physician extraordinary to the Queen. Sir Richard Douglas Powell had been physician extraordinary to the Queen since 1887. He is, as is well known, one of the greatest living authorities on diseases of the respiratory organs, and is the author of several text-books. He was made a baronet in 1897.

Heat Wave in Australia.—A heat wave is reported from Australia, causing many deaths, injuring vegetation, and originating bush fires. The thermometer in some places has, it is said, risen to 120° in the shade.

Site for Marine Hospital.—Secretary Gage has sent to congress a recommendation that $100,000 be made immediately available for reclaiming some three acres of plots in New York harbor adjacent to Ellis Island, as a site for a marine hospital.

Plague in a Russian Province.—The Vienna *Tageblatt* says that hundreds of deaths from plague are occurring in the Russian province of Astrakhan on the Caspian Sea, and that one hundred and twenty doctors have left Odessa for the field of the disease.

Anti-Spitting Notices.—The New York board of health is determined to do its utmost to stop the disgusting and dangerous habit of spitting in cars, ferry-boats, and in public buildings. President Murphy has again directed that a copy of a form of notice, in respect to spitting in public, be posted in a conspicuous place in all public conveyances and buildings.

New Law Regarding Cadavers.—A bill has been introduced into the legislature by Mr. Stewart, amending the law requiring governors, keepers, or wardens having control of prisons, hospitals, and asylums to turn over all cadavers to medical colleges in Tioga, Tompkins, Broome, Chemung, Schuyler, Monroe, Seneca, Steuben, Wayne, Yates, and Ontario counties.

Noble Germans Down with the Measles.—In consequence of attending the obsequies of the late Grand Duke of Saxe-Weimar, a number of persons of high rank contracted the measles in the infected schloss. The Duke Regent of Mecklenburg-Schwerin and the Duchess, who is a daughter of the late Grand Duke, are down with the disease, as is also the young Grand Duke of Saxe-Weimar himself.

To Abandon Randall's Island.—The State board of charities in a special report to the legislature recommends that the House of Refuge on Randall's Island be removed to the country, and that the girls' department of the institution be discontinued, the older girls being sent to the new reformatory at Bedford, and the younger ones to the New York Juvenile Asylum and the New York Catholic Protectory, or like institutions; also that this institution be placed under the rules of the State civil-service commission.

Medico-Chirurgical College and Hospital.—The board of trustees of the Medico-Chirurgical College and Hospital of Philadelphia has been reorganized by the election of the following members: *President*, former Justice Paxson; former Justice Sterrett, Judge

Beitler, Hon. J. A. Logan, Pemberton S. Hutchinson, Joseph L. Caven, Henry D. Paxson, David Milne, W. Howard Pancoast, Theodore P. Voorhees, George A. Huhn, John A. Grady, William King, D. T. Pratt. The membership of the old board was as follows: Drs. John V. Shoemaker, James M. Anders, Ernest Laplace, W. Easterly Ashton, L. Webster Fox, William E. Hughes, William L. Rodman, Isaac Ott, Henry Fisher, W. F. Haehnlen, George M. Boyd and W. C. Hollopeter, Samuel Disston and William King.

The Cost of Alcoholism in Paris.—The Paris *Journal de Médecine*, writing on the waste caused by alcoholism, points out that hospital statistics alone show that inveterate drunkenness in itself costs the city at least 2,000,000 francs per annum, through the lost labor of the individual and through the expenses connected with hospital treatment.

Reduction in Mortality from Diphtheria due to the Use f Antitoxin.—The report of the Lancaster (Pa.) board of health for the year 1900 shows that there were but 28 deaths among 252 cases of diphtheria treated during the year—largely with antitoxin—as compared with 63 deaths among 260 cases in the year 1892, when no antitoxin was used, and with 68 deaths among 229 cases in 1895, and 38 deaths among 197 cases in 1899.

Philadelphia County Medical Society.—At a stated meeting held January 23d, Dr. Albert E. Roussel read a paper entitled "Report of Three Cases of Malignant Endocarditis: One following Measles; One following Typhoid Fever in a Child and Simulating Splenic Lymphatic Leukæmia; and Another Terminating in Recovery." Dr. John B. Roberts read a paper entitled "Epiplopexy in Cirrhosis of the Liver," reporting two cases in which he attached the omentum to the parietal peritoneum for the purpose of establishing a freer collateral circulation through the abdominal veins. One patient died shortly after the operation and the other survived for six months without recurrence of the ascites. Dr. Albert Bernheim read a paper entitled "Albuminous Nutrition and Nutritious Albumin." Dr. John B. Roberts was elected censor to fill a vacancy caused by the election of Dr. Thomas H. Fenton as first vice-president.

First Municipal Crematorium in Great Britain.—The first crematorium erected by any muncipality in England was opened in Hull, Yorkshire, in the first week in January. The cremating apparatus is a furnace of the regenerative type designed by the late Mr. Simon, of Manchester. The degree of heat can be regulated in the most exact manner. There is no smoke, and little visible flame before the body is introduced, and if the coffin is made in accordance with the regulations there is no smoke and no noise during cremation. The process occupies about an hour, at the end of which there remain only the inorganic bases of the bones, in the form of silvery gray pumice-like fragments. These are removed by passing an asbestos brush through the chamber which causes the remains to fall through an opening into the urn which is to receive them. Undoubtedly graveyards in or near great cities are more or less a menace to the health of the inhabitants. Cremating is in every particular a more sanitary mode of disposing of the dead than earth-to-earth burial. It is probable when the public become conscious of this fact, and when prejudices arising from religious scruples and sentiment have died, that cremation, in towns at least, will take the place of the older method.

The Charities Department and Blackwell's Island.—The charities department, owing to the crowded condition of its institutions, is anxious to get possession of the building on Blackwell's Island now occupied as the women's pavilion of the State Hospital for the Insane. There are five wooden pavilions, two brick structures, and one of stone. The State was ordered to vacate these five years ago, and was given until February 28, 1901, to make other provisions for the patients. The State Commissioner of Lunacy has informed Commissioner Keller that he will move as many patients as possible to Ward's Island, but asks for an extension of time until the new structure at Central Islip, L. I., is ready.

Sanitary Condition of Sydney and Nurses' Complaints.—The latest reports from Australia do not convey a pleasing impression with regard to the state of affairs in Sydney. In spite of the warning given them by the plague, the authorities do not appear to have realized the true situation and their own responsibilities. The perfect climate is always brought forward as a great inducement for emigrants to go to the land of the Southern Cross, but this advantage is more than counterbalanced in the cities by the disgraceful condition of the streets, where filth and garbage are permitted to rot. In the report on the health of Sydney for the quarter ending September 30, 1900, Dr T. Mailler Kendall stated that the number of deaths from diphtheria, phthisis, diarrhœa, and typhoid showed a marked increase, being one hundred and sixty-six in advance of the corresponding period in 1899, and he asserted that the high rate would continue so long as the present system of scavenging and the removal of house garbage continued. The rubbish receptacles required remodelling in order that the emanations from decomposing matter might not pollute the city. The hours of labor of the nurses of the Sydney Hospital have been brought under the notice of the legislative assembly. According to the Sydney *Daily Telegraph* of November 28th, Mr. Holman informed the assembly that the nurses were kept at work for no less than eighty hours per week, with only one full holiday of twenty-four hours in the year. The Premier said that he had already heard rumors with regard to the way in which the nurses of Sydney Hospital were treated, and he had given instructions that these ladies were not to be worked like slaves.

Faulty Statistics in Brooklyn.—According to the head of the bureau of records of the Brooklyn health board, says the *New York Times*, the excess of deaths over births shown year after year in the reports of the Brooklyn statisticians is due simply to the fact that, while every death of a necessity finds a place in the

tables, a considerable number of births are never recorded. This may relieve Brooklyn from the suspicion of abnormal insalubrity, but it reveals that something rather serious is the matter with the law or those whose duty it is to enforce it. There is little less reason for insisting upon an accurate and complete recording of births, than for a similar recording of deaths, and laxness in the one direction opens the way to abuses almost as serious and dangerous as would result from laxness. These remarks are very true. The keeping of accurate vital statistics is a very important matter, and those in control of the health board of Brooklyn should use their utmost endeavors to bring about this consummation. The physicians of Brooklyn—with whom it is suggested that some of the blame for this state of affairs lies—would do well to co-operate with the bureau of records by giving in every case of birth a certificate.

Land for Scientific Purposes in New Mexico.—A bill has been introduced in the House of Representatives directing the general government, through the secretary of the interior, to secure title to the cliff-dwellers' region of New Mexico for park and scientific purposes, and one in the Senate, appropriating $5,000,000 for the purchase of land in the Appalachian Mountains for a national forest reserve.—*Science.*

Philadelphia Hospital.—In addition to the reelection of the former members of the medical staff, the following appointments were made at a meeting of the Bureau of Charities and Correction on January 24th: To the neurological department, Drs. F. Savary Pearce, William G. Spiller, Charles S. Potts; to the children's department, Drs. William C. Hollopeter, E. E. Graham, J. P. Crozer Griffith, J. Madison Taylor; to the department of orthopedic surgery, Drs. J. P. Mann and G. G. Davis; to the laryngological department, Drs. E. B. Gleason and Charles P. Grayson; to the ophthalmological department, Dr. John W. Croskey.

South African Hospitals Vindicated.—The British Royal Commission appointed to investigate the validity of the charges brought by Mr. Burdett Coutts and others against the management of the hospital in South Africa has just completed its work. The findings are contain d in a voluminous report, the gist of which is that, taking the campaign as a whole, it cannot be truthfully asserted that the medical or hospital arrangements broke down. The report declares that nothing in the nature of a scandal has occurred in regard to the care of the sick and wounded, and that there has been no general widespread neglect. Witnesses who had experience in other wars were almost unanimous in the opinion that when everything has been taken into consideration, the sick and wounded had never been so well tended in any other campaign.

Absinthe Legislation in France.—In the course of the past six years the consumption of absinthe in France has nearly doubled, the annual amount drunk being now something like ten million litres. The increase of the drinking habit in France has for long been a source of grave alarm among its thinking men and enlightened legislators. The advocates of temperance have been working quietly but energetically to procure laws in France which shall have the tendency to reduce the sale of drink, and especially of absinthe. This movement has already had the practical effect of inducing the French chamber of deputies to adopt a unanimous resolution calling upon the government to prevent the manufacture and sale of alcoholic liquors pronounced as hurtful or dangerous by the Academy of Medicine. France has only recently been brought to a realization of the risk to the national health and prosperity incurred by the misuse of absinthe, and she is without doubt suffering not only from the evils of absinthe drinking, but also from an undue consumption as a people of other alcoholic beverages.

The Chicago Drainage Canal.—According to reports, the pessimistic prophecies with regard to the Chicago canal have up to the present not been fulfilled. On the contrary, the Illinois River is said to be a purer stream since the opening of the drainage canal than before. The noxious elements in the Chicago sewage have been eliminated within a distance of one hundred miles from the city. The dilution of the sewage with the waters of Lake Michigan has benefited the Illinois valley and improved the quality of the water. The contention of St. Louis, that running water does not purify itself, has been effectually and emphatically demonstrated to be untrue by three independent analyses of thousands of samples of water taken from the stream below the Robey Street entrance to the drainage channel and the water works above the city of St. Louis.

Obituary Notes.—Dr. James Watson Stronach, formerly of New York, died suddenly on January 23d, at his residence in Belleville, N. J. He was sixty-seven years old. Death was due to heart trouble. Dr. Stronach was born in Forres, Scotland, and came to this country in 1860. He was graduated from the College of Physicians and Surgeons in New York in 1872. He had resided in Belleville about a year.

Dr. Eliphalet Nott died at his home in Rexfords Flats, Saratoga County, N. Y., on January 22d, aged sixty-seven years. He was a nephew of the Rev. Dr. Nott, for many years president of Union College.

Dr. Lillian R. Safford died at York, Pa., on January 21st. She was a graduate of the Women's Medical College of New York.

Dr. Frederick G. Bloom died of pneumonia at Martinsburg, Pa., on January 24th. He was one of the oldest graduates of the University of Pennsylvania, and had been engaged in the practice of his profession in Martinsburg for more than sixty years.

Dr. J. Stuart Leech died on January 23d, at Downington, Pa., where he had been engaged in the practice of medicine for fifty years. He was the oldest practising physician in Chester County.

Dr. H. L. Stickel died on January 24th of pulmonary tuberculosis, at Harrisburg, Pa. He was a graduate of Jefferson Medical College.

Dr. William Simpson, of 127 West Forty-fourth Street, committed suicide on Saturday, January 26th,

by shooting himself in the right temple. Dr. Simpson was house physician of the Gerard Hotel.

Dr. H. D. Reardon, a physician, was found dead in bed at Elmira recently. Death was due to an overdose of chloroform.

Dr. Richard Thorburne, of Colborne, Ont., a well-known member of the medical profession in Canada, passed away on December 10th.

In the first week in January several distinguished medical men died in Paris, including Dr. Bérenger-Féraud, formerly médecin-en-chef to the navy, and president of the Conseil Supérieur de la Marine. The death is also announced of Dr. de Beauvais, one of the oldest Paris practitioners, who died at the age of seventy-nine years, and last and the most eminent of all, Professor Potain. The last-named physician died suddenly at the age of seventy-five years. He had retired from active work only six months ago, at which time he delivered his last lecture at the Charity Hospital amid a scene of almost unparalleled enthusiasm and affection. Professor Potain, over and above his scientific attainments, was a kindly hearted man of the old-fashioned, courtly school.

Progress of Medical Science.

New York Medical Journal, January 26, 1901.

Septicæmia, Acute Bacteriæmia and Pyæmia, Chronic Bacteriæmia; the Indications for Hysterectomy and the Indications for Abdominal Section and Drainage in Puerperal Infection.—From a review of recent literature H. J. Boldt would adopt the following definitions: Septicæmia (acute bacteriæmia) is a blood disease caused by parasitic microorganisms invading the circulatory system from some primary seat of infection, the infection producing elements multiplying so rapidly in the blood that the patient generally succumbs within five days after the disease begins. Usually the parasitic germ is the streptococcus pyogenes; other pathogenic germs may, however, be present also. Pyæmia (chronic bacteriæmia) is likewise caused by the invasion of the system by the streptococcus pyogenes alone or in conjunction with other pathogenic germs, but they disseminate from an infected thrombus. They are not diffused into the system in one large quantity, neither are they possessed with the same foudroyant virulence from a clinical viewpoint. The production of the abscesses found in the condition called pyæmia, upon which the pathological difference between the two conditions depends, is due to the parasitic organisms finding a resting-place outside of the blood circulation, and there giving rise to abscess formation. The indications for hysterectomy, under the conditions stated, he gives in the following rules: (1) If, after a full-term delivery or an abortion, there are no conception products in the uterus, and the patient has fever with exacerbations, chills, and a small and frequent pulse (120 to 140 or more), if careful observation should show that the infection comes from the uterus alone, that organ being enlarged, and relaxed in its consistency, if there is no evidence of peritonitis, the parametria being free, if streptococci are found in the uterus, and, especially, if the blood shows the presence of pathogenic germs, as in Prochownick's patients. (2) If there are decomposition products in the uterus, which cannot be removed satisfactorily per vaginam; if, on doing a Cæsarean section, the uterus is found septic, then an abdominal hysterectomy is indicated. Abdominal section with drainage is indicated in diffuse septic peritonitis when there is no evidence of an exudate in the pelvis. The annexa are to be left undisturbed unless there is some positive indication to remove them.

Gastro-Enterostomy by the Elastic Ligature.—After giving a history of the introduction and development of this device, T. A. McGraw narrates several clinical histories, laying special emphasis on the necessity of a proper technique. He lays down the following rules: (1) The ligature. This should not be a rubber thread nor a flat band; these lack the necessary strength to cut their way with certainty through the thick walls of the stomach. The surgeon must use a hard, round, smooth, and strong rubber cord, at least two millimetres in diameter. (2) It must include in one loop all of the tissue which it is desirable to sever. The formation of several small connected loops is an error. In general, the larger the amount of tissue included in the loop the quicker and more certainly will the ligature perform its work. (3) The cord must be drawn as firmly and tightly together as possible, and fastened by a silk thread, which is tied around it. He has himself tied the rubber first in a single knot, fastened the silk around it, and then repeated the process for the sake of greater security. This may not be necessary, as the knotting of the silk thread once would probably serve the purpose. (4) Before the rubber ligature is inserted the viscera should be joined together by a row of Lembert sutures for a distance of six or seven centimetres, and when the ligature has been tied a similar row in the front should complete the junction. If ever there should be an ill success with the ligature, it will, he believes, occur from its too rapid action. The failures to cut through observed by certain German surgeons have been due to some fault in the technique.

Treatment of Influenza.—W. H. Thomson advocates the use of a pill containing gr. $\frac{1}{12}$ solid extract of aconite, gr. ss. Dover's powder, gr. ii. phenacetin, and gr. iss. quinine, two pills to be taken thrice daily as long as fever is present. The dosage is then to be gradually reduced by one pill until the catarrhal symptoms have passed away. For coryza and nasal symptoms gr. $\frac{1}{4}$ belladonna with gr. ii. camphor are of service. The passages may be flushed with two teaspoonfuls of chlorate of potash and five drops of oil of peppermint in a quart of hot water. Ergot may be given for the supraorbital pains, a drachm of the fluid extract every three hours. For the persistent cough he advises bromide of ammonium gr. xx. with antipyrin gr. x. To clear out the bronchi he gives morphine gr. $\frac{1}{12}$ with chloral gr. viii. added to an emulsion of linseed oil. The patient should go to bed at once and stay there until further orders.

Cereals, Emulsions, and Proteids in Infant Feeding.—T. M. Rotch believes that the only value of adding cereals to infant food, that is, milk, lies in the fact that their presence assists in the finer subdivision of the caseinogen coagulum and that the same effect can be produced by modern methods which are much less irrational. He is disposed to favor emulsions as being at least harmless. He believes further that the management of the coagulum depends on the management of the caseinogen, and that the coagulum will be small and fine if the caseinogen is kept down to its proper relative proportion to the whey proteids; also that by using whey we can obtain these desired percentages of whey proteids, and that in all probability it will in the future be proved that by using whey the coagulum will be finer than that obtained from the use of barley water or any other cereal diluent.

Observations on the Toxic Effects of Some Common Drugs.—By P. H. Harvey.

Journal of the American Medical Ass'n, Jan. 26, 1901.

The Unbroken Skin as an Absorbing Medium.—Thomas F. Reilly states that after many experiments and various theories concerning this subject Waller and others discovered that many substances, which of themselves could not produce constitutional effects when applied to the skin, might be absorbed if dissolved in a volatile substance, such as ether, chloroform, or alcohol, which itself is absorbed in a volatile state. The absorption of aqueous solutions of non-volatile bodies by the normal skin is practically impossible. Whatever absorption takes place in the mineral baths is due to the transmission of the gases evolved and to the presence of exposed mucous surfaces, such as those of the rectum, vagina, etc. The following agents may be absorbed through the skin and produce constitutional effects: mercury, iodine, europhen and iodoform, salicylic acid, silver, quinine, phenacetin, turpentine, guaiacol, creosote, croton oil, ichthyol, pilocarpine, digitalis, belladonna, and carbolic acid. It is customary to give the dosage as two or three times that of the same drug when administered by the mouth. A medicinal agent to be absorbed by the unbroken skin must either become volatile during its application or be incorporated in a fatty base and applied with friction. Occlusion is an absolute requirement in the case of volatile substances. Most of the absorption occurs in the crypts of the sebaceous glands. The effect is much slower, about one-fourth as intense, and longer continued than when the same agent is administered by the mouth. A large number of medicinal agents, which when given by the mouth are intolerable to many patients, may be administered in this way with scarcely any unpleasant effects.

Traumatism during Intubation; its Prevention and Treatment.—Johann von Bokay states that traumatism can result during the act of intubation in three periods: during the introduction of the tube, while the tube is in place, and

when the tube is withdrawn. Traumatisms resulting from the introduction of the tube can be caused by improperly constructed tubes, although the majority are caused by carelessness during the introduction. To intubate properly, we must be thoroughly acquainted with the details of the operation. The writer advises the beginner to intubate children who are not suffering with stenosis, but rather in whom a tracheal fistula exists. Of course, the anatomy of the parts must be thoroughly mastered. Extensive practice is necessary in order to become familiar with all the details. The mouth must be stretched *ad maximum*. Some operators prefer to have the patient on his back, while others advise the sitting posture. The instruments should be in perfect order. Before the introduction of the tube it is well to wash the pharynx with a four-per-cent. boric-acid solution. The instruments should be worked in the median line. The obturator should not be pushed too soon. Great gentleness should be exercised. After a false passage is made, it is wisest to remove the perforating tube and to follow it immediately by a secondary tracheotomy. It is possible that without repeated intubation or a secondary tracheotomy healing may result.

Some Remarks on the Plantar Reflex, with Especial Reference to the Babinski Phenomenon.—J. T. Eskridge concludes that: (1) The Babinski phenomenon is an extremely valuable sign in diagnosis, and probably in prognosis and prevention. (2) It is not a pathognomonic sign of organic disease of the lateral tract. (3) We shall learn by subsequent observations that several poisons or conditions so irritate the lateral tract as to cause a pseudo-Babinski phenomenon, or an apparently genuine one temporary in character. (4) Greater care should be used by the investigator, and the carefully studied cases should be much more numerous.

The Lancet, January 19, 1901.

An Account of the Epidemic Outbreak of Arsenical Poisoning Occurring in Beer Drinkers in the North of England and the Midland Counties in 1900.—By E. S. Reynolds. Under symptomatology the author enumerates findings as to complaint of patient, aspect, skin lesions, nervous system, circulatory system, respiration, digestion, urine, and temperature. From his study of a large number of cases it seems clear to the author that arsenic is almost certainly a cumulative poison, although some authors say that it is not so. Moreover, it is a poison which affects both the skin and the respiratory and digestive mucous membranes, the nerve trunks, both sensory and motor, and the muscles (including the heart muscle) and the liver. The sequence of symptoms is: (1) Digestive symptoms; (2) laryngeal catarrh, bronchitis, and acute skin symptoms; (3) disturbances of sensibility; and (4) motor paralysis (and pigmentation and keratosis). In general it may be said that the course of the disease is a slow one. The gastric, coryzal, and laryngo-bronchial symptoms pass off first, then the acute skin lesions, which pass on to the chronic skin lesions which last many months. The erythromelalgia and sensory symptoms are almost as marked as ever in patients under observation for four or five months, and judging from analogy of so-called alcoholic paralysis the motor disturbances will last for from eighteen months to two years before they entirely disappear. In general grouping the division of the cases was as follows: (1) Those with all symptoms fairly well marked; (2) those with skin lesions principally; (3) those with cardiac and hepatic lesions principally; and (4) those with paralytic lesions principally. Treatment was symptomatic. A caution is uttered against the use of any cardiac depressants. The drugs offering the best results were found to be digitalis, strychnine, gastric sedatives, ammonium carbonate, senega, and morphine.

The Roentgen Rays and the Diagnosis of Urinary Calculi.—By C. Mansell Moullin. After expressing his conviction as to the great utility of this means of diagnosis, the author mentions some of the difficulties in practical application. One of these is the patient's breathing. The kidneys move up and down during even tranquil respiration to a much greater extent than is usually believed. They are not by any means immovable organs, as any one who has ever exposed a kidney during life must know. The patient cannot hold his breath for a sufficient length of time. The plan of making him hold his breath with the thorax fixed in a certain predetermined position, for short periods, at frequent intervals, and allowing the exposure to take place only at those periods, answers fairly well, but requires a very careful patient. A more satisfactory plan is either to direct the patient to take very shallow breaths, or, better still, to put a firm bandage around the abdomen. This fixes it in a position of expiration and has the additional advantage of slightly raising up the opaque mass of the liver. The respiratory movement is less when the patient is sitting upright, but this advantage is more than compensated for by the way in which the abdominal viscera descend and conceal the kidneys. In the case of a very prominent abdomen the prone position, with the plate beneath, has been recommended instead of the supine position, with the idea that the abdomen would be flattened out to the sides and the kidneys brought nearer to the plate. Distention of the bladder with air in the case of a fixed vesical calculus is certainly of use, and provided the air is sterilized first, and due regard is paid to the sensations of the patient, it may be practised with no more danger or unpleasantness than that which attends the process of washing out the bladder.

Urotropin as a Urinary Antiseptic.—By P. J. Cammidge. The author's views are expressed in the following: As a urinary antiseptic urotropin appears to be much superior to those usually employed (*e.g.*, salol, ammonium benzoate, boric acid, guaiacol, naphthalin, and resorcin), especially when the acidity of the urine is insured by suitable means. It is not, however, only in the ordinary forms of urinary infection that the advantages of the drug as a curative agent are so apparent, but in typhoid fever it may be employed from the third or fourth week onward to the advantage of both the patient and the community at large. Recent researches have shown that typhoid bacilli occur much more frequently in the urine than has been generally supposed and that they may persist for very long periods after convalescence (five years). By the systematic use of urotropin in all cases the very real danger from this source which is so frequently overlooked may be entirely avoided.

Infective Parotitis after Abdominal Section.—By W. Elder. A man aged twenty years was operated on for appendicitis and did well till the third day, when one parotid began to swell with the customary signs and symptoms, the surrounding tissues all being enormously swollen. In the course of thirty-six hours the other gland took on similar features. The swellings on both sides were very painful to pressure but did not suppurate. Seven weeks before there had been a case of mumps in the house where the patient lived when taken sick with the appendicitis. The author is inclined to think that one can hardly exclude infection from the first case as the cause of the second.

A Case of Gangrene of the Penis.—By G. A. Clarkson. The patient was a man aged fifty-one years, who suffered for a long time from chronic bronchitis and emphysema. The heart action was weak and irregular and the vessels were tortuous and rigid. He was suddenly seized one day with collapse from which he gradually rallied, but presented evidences of cystitis and probable kidney lesions. On the thirteenth day after the seizure he began to have pain in the penis which was greatly swollen. Two days later patches of gangrene began to appear, gradually involving the whole organ. Death occurred three days later.

Spoon-Shaped Indentations in the Skulls of the New-Born.—J. M. Munro Kerr states that indentations of the fœtal skull may be either spoon or furrow shaped. The

occurrence of these two varieties is of about equal frequency. The furrow-shaped variety is far less serious and seldom gives rise to much immediate trouble. The spoon-shaped indentation is generally situated on one or other parietal or frontal bone, near the anterior fontanelle. This deformity occurs, with few exceptions, when there is a deformity of the maternal pelvis, rickets being the most common cause of such. When a deformity of the pelvis exists the indentation is usually caused by the head being pressed against the projecting sacral promontory. Most writers are now agreed that forceps have directly very little to do with the production of depressions. Occasionally two depressions may be found in the same skull, then the one is usually smaller than the other and placed opposite to it. Generally speaking the prognosis is not unfavorable. If the children are born alive the indentations in the majority of cases disappear in a week or two, having given rise to no trouble at the time, and producing no ill-effects later. In a certain number, however, the depressions remain and are a permanent deformity. In such cases there are usually no disturbances, although occasionally there may be minor nervous storms. For the immediate relief of depressions of the fœtal skull many devices have been tried; thus, such things as exhaust pumps and cupping-glasses have been advocated. Trephining has been done with elevation of the depression. The writer then reports a case of his own in which there was a deep spoon-shaped depression of the right frontal bone. The head was firmly compressed antero-posteriorly, and on the first attempt the depression came out, producing a sound as when a dent in a felt hat is removed.

A Note on the Occurrence of Abortion.—J. B. Hellier reports the following statistics taken from gynæcological patients having in most cases some pelvic disorder, so that the tendency among them to miscarry would be above the average for all married women. The 1,800 women had given birth to 6,974 children, an average of 3.87 each. They had had, according to their own statement, 1,288 abortions. This amounts to about one abortion to every 5½ children. The number of women in the 1,800 who had had abortion but no children was 58. Deducting from the 1,800, 184 women who had never been pregnant, 1,616 remain. So that of 1,616 women who had been pregnant, 58 had had one or more abortions, but had never gone to term. Thus it follows that among a group of women in whom the frequency of abortion might be supposed to approach the maximum, 96.5 per cent. of those who became pregnant did sooner or later bear one or more children at term.

A Clinical Lecture on Diagnosis in Cancer of the Body of the Womb.—M. Handfield-Jones gives the following conclusions: (1) That in cases of corporeal cancer there is a stage of benign adenoma. (2) Uterine scrapings are not perfectly reliable, owing to the tissue being only superficial, and the deep part of the gland not being obtained. Later scrapings, when the disease is more advanced, are therefore more reliable. (3) Clinical signs are more valuable than microscopical evidence. (4) The degree of malignancy varies much, and the disease may run a very slow course. (5) Rapid increase in the size of the body of the womb is the most valuable sign in determining need for extirpation of the whole organ.

Foreign Body Long Retained in the External Auditory Meatus.—J. B. Curgenven remarks that it is astonishing how long a foreign body may lie in the external auditory meatus without setting up inflammatory action. The writer then reports the case of a girl aged sixteen years, who claimed to have been deaf in the right ear as long as she could remember. On examination, the ear appeared full of dark-colored wax. After the ear was syringed a hard body was felt by a probe. With some difficulty this was extracted by forceps and proved to be an acorn. The patient had no remembrance of the introduction of the body.

Treatment of Acute Broncho-Pneumonia of Childhood.—Among the directions given by Carrière for the treatment of this disease are the following: I. Prophylactic measures, indicated in the course of infectious maladies which are often followed by broncho-pneumonia, are: (1) To isolate the patient as much as possible; (2) to avoid chills; (3) to place the patient in a chamber which can be aired as much as possible; (4) to make the air which the patient breathes aseptic by antiseptic vapors, the following solution may be used:

℞ Phenol	20 gm.
Thymol	10 "
Benzoin	10 "
Alcohol	100 "
Water	860 "

(5) to make the respiratory tract aseptic: (*a*) by nasal instillations of mentholated oil, (*b*) by irrigations of the mouth by boric acid; (6) to care for the skin which can be the port of entry for infectious germs; (7) to care for the intestine (calomel); (8) to stimulate the organism (tonics, alcohol, baths). II. When the disease sets in: (1) The patient should be kept in bed, but should not be too heavily covered. The chamber should be well aired without chilling the child. The child's position should be often changed. (2) Alimentation: A glass of milk should be given every two hours; bouillon or beef-juice to children over eighteen months. Abundant fluid should be given. (3) The congestion of the lungs should be relieved. (4) The organism should be stimulated by baths and medication. (5) Antisepsis of the organism should be secured. (6) The emunctories of the body should be carefully looked after. (7) Complications must be treated as they arise. III. When the stage of convalescence is reached, vigilance in the care of the child must not be relaxed until complete recovery supervenes.—*Le Nord Médical*, January 15, 1901.

Polyneuritis following Grippe.—According to Diemer the history of neuritis, particularly of grippal neuritis, is of recent date. The anatomical conditions underlying polyneuritis are not well known, for only one case of this kind has been followed by autopsy. It is not difficult to explain the pathogeny of this neuritis. If grippe is an infection produced by an agent which is peculiar to it, all the phenomena which are its clinical expression are nothing else than an intoxication due to the toxins secreted by this agent. Grippal polyneuritis begins generally during the period of convalescence, like the neuritis of diphtheria to which it has been compared. After some days, perhaps some weeks, the temperature falls, the nervous phenomena properly speaking, thoracic or gastro-intestinal, have disappeared, and troubles of sensation or motor troubles open the scene. Soon there develops a more or less complete picture of peripheral polyneuritis. Motor troubles are constant in grippal polyneuritis. The parts affected by this paralysis are very variable, so that it is impossible to say that grippal polyneuritis has a predilection for any one group of muscles. It can be said that any muscle may be affected by the paralysis and that consequently the functional troubles which are its consequence vary according to the diverse modes of localization of the lesions. The reaction of degeneration is present in the muscles affected. Ataxic phenomena are frequently noticed in this paralysis. Finally, one of the last characteristics common to this paralysis is the flaccid condition of the muscles affected. As to muscular atrophy, it is generally noted but it is not very marked.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, January 13, 1901.

Asystole.—Bonsignorio states that by the term asystole is meant a combination of conditions which result from insufficiency of cardiac contractions as well as from insufficiency of cardiac circulation. This condition appears at the end of chronic heart disease, and its principal manifestations are cyanosis, dyspnœa, stasis of the blood current, congestion, œdema, and finally coma. The essential lesion of this affection is especially dilatation of the heart, notably of the right heart. The pulse is quickened for two reasons: on account of the weakness of the cardiac contractions and on account of the diminution of arterial pressure. Asystole can run a rapid or acute course, or it may be slow in its progress, subject to many remissions. It may last for years, although the lesion may declare itself definitely from the beginning. In these cases digitalis is of no avail. Acute asystole may have a fatal termina-

tion within a few hours, but this is rare. At last, after several attacks, cardiac cachexia precedes the end.—*La Tribune Médicale*, January 16, 1901.

Ano-Rectal Fistulæ Premonitory of Pulmonary Tuberculosis.—Ernest Barié concludes that: (1) In tuberculous patients ano-rectal fistulæ may precede sometimes by a very long period—several years even—the appearance of the first manifestations of pulmonary tuberculosis. (2) These ano-rectal fistulæ premonitory of tuberculosis follow in the train of abscesses appearing most often insidiously, but which may in certain cases succeed a local traumatism.—*Journal des Praticiens*, January 12, 1901.

Berliner klinische Wochenschrift, No. 1, Jan. 7, 1901.

Syphilis and Mental Affections.—Jolly enumerates as neuroses in connection with specific disease nervousness, hysteria, and epilepsy. Manifestations of the latter may be due not to the toxic effect of syphilis but to a masked gumma. Purely mental sequences are melancholia, paranoia, amentia, and dementia, in which latter the speech centre seems to be first affected. Some of the symptoms associated with the latter condition strongly suggest general paralysis of the insane. Paralytic dementia often occurs as a tertiary manifestation of specific disease.

Cutaneous Sensory Disturbances in Internal Disease, Especially of the Stomach.—Hans Haenel, following in the footsteps of Henry Head, has made extended observations on the effect which disease of the internal organs has on cutaneous sensibility. As a result he finds that under such circumstances definitely outlined zones of hyperalgesia frequently occur. These are usually to be considered reflex and serve to explain many of the symptoms commonly referred to neurasthenia, rheumatism, or hysteria. While it is true that when such hypersensitive areas are to be demonstrated any pain complained of is likely to be genuine and to be dependent on actual internal disease, the converse does not hold and no positive conclusions are to be drawn from their absence. The distribution of the hyperalgetic areas is of use in judging of the nature or location of the primary disorder only when the zones do not cover too much surface and are found constant on repeated examination. When the stomach is involved, the district controlled by the seventh to the ninth dorsal nerves is the one especially apt to show abnormalities of sensation, though no clew is given in differentiating ulcer from other affections.

Pancreatic Abscess.—Marwedel has found in the literature eight cases of pancreatic abscess treated by operation. To this number he adds a successful case which makes the sixth cure. The patient was a man aged sixty years, who for eight months had been suffering from indefinite abdominal pain coming on in spasms and being subject to protracted remissions. At one time constipation and jaundice followed an attack, but subsided under saline treatment. On admission to the hospital the patient was found much emaciated, with a rounded, deep-seated mass in the left epigastric region. The diagnosis of tumor of the pancreas was made and an exploratory laparotomy performed, when the mass was found to contain a cavity holding about a pint of pus. The diagnosis was amended to read retroperitoneal abscess situated in the peripancreatic tissue and originating in the pancreas.

The Etiology of Primary Contracted Kidney.—Oswald Baumgarten, basing his conclusions on the statistics of two hundred and twenty cases of this disease, corroborates the usually accepted views that it is a lesion of middle life, most frequent in men and caused by such factors as alcohol, lead, syphilis, and gout.

Thymic Death.—Hans Kohn collates the views of different writers who have sought to explain the manner of the sudden death sometimes occuring in children subsequently found to have enlarged thymus glands. The two most probable theories seem to be that either the hypertrophied organ produces laryngeal stenosis through its pressure, or that its internal secretion is in some way modified so as to affect metabolism, and especially the heart, unfavorably so that some comparatively trifling external cause is sufficient to produce a fatal result. In a case treated and autopsied by the author a somewhat different state of affairs was found. The patient, a child aged seven months, was moribund when first seen and died two hours later, although no definite physical signs could be elicited. On section it was found that the thymus was enormously increased in size, so that it pressed upon the aorta and caused obstruction to the blood current with secondary dilatation. The heart was dilated and hypertrophied, and the supposition is that it finally became insufficient and collapsed under the gradually increasing stress.

Vomiting after Chloroform and Other Inhalation Anæsthetics, with a Suggestion for its Prevention.—L. Lewin is of the opinion that the larger share of the nausea following the use of general anæsthetics is gastric rather than central in its origin. A considerable amount of the anæsthetic is undoubtedly swallowed, either dissolved in the saliva or in vapor, and a very appreciable irritation of the gastric mucosa follows. Two methods suggest themselves for the prevention of this effect: one preliminary anæsthetization of the lining of the stomach, and the other the introduction of some substance which shall act as a protective to the stomach wall. The first object may be attained by the administration of a considerable quantity of dilute cocaine solution, while mucilages of acacia, tragacanth, or Irish moss introduced immediately before the anæsthesia is begun would undoubtedly protect the nerve endings and prevent the irritating action of the aerial vapor.

The Etiology of Dysentery.—Deycke, working in Constantinople, which is a hot-bed for this disease, describes an organism which is always to be found in the stools, intestinal walls, and abdominal organs of dysenteric patients. Grown in pure culture it appears to belong to the group of the bacterium coli and to resemble the typhoid bacillus. Cats are especially susceptible to the germ, and after one to three days of bloody or purulent diarrhœa with extreme emaciation die with the same intestinal lesions as those accompanying human dysentery. A further report is promised for a later date.

Determination of the Lower Border of the Stomach with the Roentgen Rays.—W. Becher introduces the stomach tube with the patient in the upright position, and standing before the apparatus so that the tube, which throws a visible shadow, can be watched in its descent. If a mixture of bismuth subnitrate in water is now poured through the tube it becomes visible as an oblong shadow around the end of the instrument, and the lower boundary of the stomach is plainly demarcated.

The Causes of the Natural Resistance to Certain Infections.—A. Wassermann publishes the reports of some animal experiments which he thinks definitely prove the accuracy of the theory that the ferment-like bodies present in normal blood and having the power to destroy bacteria actually do represent a most valuable defence against infection.

The Pathogenesis of Gonorrhœal Epididymitis.—Desider Raskai describes a case in which suppuration of the epididymis took place more than a month after the acute gonorrhœal inflammation. In the pus evacuated from the abscess gonococci were found in pure culture, proving the nature of the lesion as well as the vitality and virulence of the organism.

The Oxygen Treatment of So-Called Uric-Acid Lesions.—Alfred Careno Crofton claims to have demonstrated that not uric acid, but the so-called alloxuric bases are the

cause of lithæmia, the uratic dyscrasia, gout, and allied lesions. It will, he says, depend on the activity of the oxygenation processes of the organism, whether uric acid, a non-toxic substance, is found, or whether, with deficient oxygenation, the poisonous alloxuric bases are generated instead. In treatment he finds that inhalations of oxygen give uniformly good results. A safe average plan is to give inhalations daily for a week, every other day for two weeks, twice a week for two weeks, and then a weekly inhalation for from one to four weeks more. The good effects persist for months. The diet should be regulated so as to forbid foods that contain alloxuric bases, syn. "nitrogenous extractives," nuclein, or those that are capable of producing a leucocytosis. The indications for drugs are twofold: (*a*) To increase formation and prevent disintegration of red blood corpuscles and their chief oxygen carrier, hæmoglobin; (*b*) to encourage rapid elimination of the alloxuric toxins.

The Uric-Acid Diathesis.—James Tyson holds that the uratic diathesis is remediable in two ways: first, by limiting the ingestion of nitrogenous food, whence uric acid and its congeners are derived; second, by increasing the quantity of the water constituent of urine and by alkalizing the blood and urine with a view of favoring solution and elimination of uric acid. There is no contraindication to the use of carbohydrates and hydrocarbons, provided they do not produce acid fermentation. Nor is there any objection to the use of fruits which are not acid. Exercise, bathing, and massage should also constitute part of the treatment. The alkaline bases should be administered, principally the salicylates, the citrates, and bicarbonates.

Finska Läkaresällskapets Handlingar, December, 1900.

Cysts of the Middle Turbinated Bones.—Albert Sundholm observes that bone cysts for the most part escape observation, although they are of fairly frequent occurrence—a fact which he attributes to their being small, and unaccompanied by marked symptoms. He reports three cases, two of women, one of a man. The whole literature of the subject contains only two cases of men. In one of the cases the cyst was egg shaped and 4 cm. long. The author holds that these cysts are merely aberrant ethmoidal cells developed in the middle turbinated bone.

Double Vagina with Single Uterus.—O. A. Boije reports four cases. He concludes from a microscopical examination of the septum in each case, that these septa are due to imperfect amalgamation of the lower part of Mueller's ducts, during the early months of fœtal life. Nagel, on the contrary, held that a vaginal septum with a normal uterus was due to an amalgamation of two folds of mucous membrane during the second half of fœtal life. Were this the case, Boije remarks, there would be traces of cicatrization or of other tissue changes.

Cirrhosis of the Liver in a Boy of Eight Years.—Max Björkstén reports a fatal case in which the post-mortem findings bore out the diagnosis of cirrhosis of the liver. The author advises determination of the amount of albumin in the abdominal exudate (if there be any), to establish a differential diagnosis between tuberculous peritonitis and cirrhosis.

Vaginal Hysterectomy and Resection of the Vagina in Cases of Uterine Prolapse.—By Axel Wallgren.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-fifth Annual Meeting, Held in Albany, January 29, 30, and 31, 1901.

A. M. PHELPS, M.D., OF NEW YORK, PRESIDENT.

First Day.—Tuesday, January 29th.

President's Inaugural Address.—DR. A. M. PHELPS presented this address, and followed the usual custom of making certain recommendations regarding the work of the society. It was recommended that the position of assistant secretary be created, and that each county society hereafter elect two delegates yearly, for a term of one year. This, he thought, would increase the membership of the society fivefold. It was also suggested that the State society hold in the fall of each year, in one of the cities of the first class in the State, a semi-annual meeting, from which executive business should be excluded. He characterized the bill recently introduced by Senator Grady, to protect hospitals from suits for damages, as vicious, and one which the society should make strenuous efforts to defeat. He stated that it had originated with two immensely wealthy hospitals, one of which was now being sued for $25,000 damages. In concluding his address, the president suggested the organization of an "Atlantic Coast Medical Society," and that the society officially indorse the action taken by the tenement-house committee for the correction of tenement-house abuses.

Report of the Committee on Hygiene.—DR. H. R. HOPKINS presented this report. It referred to the gratifying progress that had been made toward State control of consumption, and the better housing of the poor. In view of the prevalence of gonorrhœa and syphilis, and their dreadful consequences, the committee thought it would be desirable to include these maladies in the list of diseases requiring notification and registry with the health authorities. Reference was made to the grand object lesson afforded by the experience of Schenectady and Albany in the reduction of the mortality from typhoid fever as a result of changes made in the system of water supply in accordance with the light shed by modern sanitary science.

Report of Committee on Legislation.—DR. FRANK VAN FLEET presented this report. It was stated that during the year 1900 no less than two hundred and sixty-eight bills having medical interest had been presented to the legislature. Of these, sixty-three had received the approval of both branches of the legislature, and forty-six had received the approval of the governor. No bill had become a law which was unfavorable to the society as a body or the profession as a whole. The "medical practice act," now before the legislature, the object of which is to secure a proper definition of the practice of medicine, was referred to at length and the society was asked to indorse it. The society, after free discussion, voted to indorse the principle embodied in this bill, and appointed a committee to appear before the legislature in its behalf.

Address of the President of the American Medical Association.—DR. CHARLES A. L. REED, of Cincinnati, Ohio, the president of the American Medical Association, having been introduced and most cordially received, addressed the society as follows:

"Mr. President, and Fellows of the Medical Society of the State of New York. I call you 'fellows' in a spirit of fellowship, because I have been one of your fellows, much to my gratification, for the last ten years. It affords me extreme pleasure to appear before you to-day in response to the cordial invitation of your president. When it was my privilege to appear for the first time before this distinguished body ten years ago this day, I came simply in my capacity as an humble worker in the ranks of the profession; to-day I am introduced to you as the president of the national organization, although a no less humble worker. The terms in which I have been presented to you enforces upon me the duty of extending to you, in the most cordial spirit, the greetings of the American Medical Association. I have been informed that such messages have been a trifle unusual in the past (laughter), and I almost feel that I am in a foreign country, yet it seems to me that you are wrestling with precisely the same problems which have confronted us in Ohio, and the medical profession of all the other States. For a proper solution of this it has been found necessary to have the absolute unity and co-operation of the entire profession. If the American Medical Association stands for one idea over and above another, it is for the unity and for the solidarity of our great national

profession. If there is to-day one spirit actuating it over and above another, it is the spirit which I have expressed in the words just pronounced. This is the one assurance which I bring you, and I am satisfied, from the expressions which I have heard in Albany, that that sentiment is very cordially reciprocated.

"I am sure, when you gather in our national council in St. Paul, we shall be nearer an understanding on the unfortunate questions which have divided us for nearly two decades, than we have been these many years.

"I am gratified, indeed, to notice the expressions which have cropped out in these proceedings this morning, to which I have been a very attentive listener, as they indicate that there is a disposition in your body to be democratic, and to bring within the fold of this society the workers in the ranks of the profession. In my various goings about the country, I have found that those societies seem to be doing the most good and accomplishing the greatest results that have been able to bring within their ranks the largest number of the medical profession. The weak man needs the society, and the strong man is needed by the society, and hence we need them all, but the society must be given a proper degree of respectability. Therefore, I view with satisfaction the initial step which you have taken to-day, looking to the broadening of your influence within the limits of your own State, feeling sure that that influence and that solidarity will sooner or later inure to the benefit of the great national body of the profession. I thank you, Mr. President, for your cordial reception." (Prolonged and hearty applause.)

Report of Committee on Prize Essay.—Dr. A. Jacobi reported for this committee that the prize this year had been awarded to the essay entitled "On the Management of the Interocular Base Line and the Size of the Meter Angle." The successful essayist was found to be Dr. Lucien Howe, of Buffalo.

Report of Committee on State Board of Medical Examiners.—Dr. M. J. Lewi, of New York, presented this report. It was stated that 792 candidates for license had presented themselves, and of this member 143, or 18.05 per cent., had been rejected. Before the board of the State Medical Society 710 candidates had appeared, of whom 132, or 18.59 per cent., had been rejected. Before the Homœopathic board 58 candidates had appeared, of whom 5, or 8.6 per cent., had been rejected, while of the 24 candidates coming before the Eclectic board, 6, or 25 per cent., had been rejected. The regents had licensed 107 physicians during the year. There was reason to hope that by next year one neighboring State would have made it possible for us to *visé* their licenses, and so establish a much-to-be-desired reciprocity.

Recent Progress in the Treatment of Acute Lobar Pneumonia.—Dr. James K. Crook read a paper with this title. He stated that considerable activity had been shown in this field during the past year, upward of fifty references to medical journal articles, devoted to the therapeutics of pneumonia, being contained in the Bibliographia Medica for the preceding twelve months. It was not apparent, however, that any striking innovations in our present methods of treatment had been made, nor was any great advance perceptible in the recently proposed therapeutic measures. The profession stood at variance regarding many minor questions in the management of pneumonia, but the reader of the paper had been gratified to observe a practical unanimity of opinion concerning many of the fundamental principles of treatment. The best sense of the profession, he thought, could be summed up in these admonitions: Put your patient to bed in as cheerful and well-ventilated a room as circumstances will allow. Give him nourishing food, easily digested, but not too abundant—then watch. These were the only routine measures which were indicated in all cases without exception. In the present state of our knowledge, not a single dose of medicine should be given to a patient simply because he has pneumonia. The indications should be watched for. Recent observers were by no means fully agreed as to the best methods of meeting the indications, but the careful practitioner could easily find a safe outline of action suitable for most of the emergencies likely to arise. The reader of the paper had been struck by the general indorsement of the lately almost obsolete procedure of blood-letting in pneumonia. Professional opinion was plainly undergoing a transition regarding the measure. Venesection was at this time evidently undergoing a discriminating revival. All late writers of experience admitted that there were emergencies in the disease in which the speedy abstraction of a few ounces of blood constituted the only sure means of relief for an overcharged and staggering heart. The use of cold applications—ice bags and sponge baths—was happily becoming almost universal. No procedure in the whole range of pneumonia therapeutics could be more safely applied or was followed by more grateful effects. The old-time poultice was being relegated to a well-deserved oblivion. Arterial sedatives were also losing favor, although still advocated by several trusted teachers. The use of opiates was indorsed by some, decried by others. In the conflicting state of opinion, Dr. Crook thought it a wise plan to look for positive indications for their use—obstinate insomnia, intense nervous excitation, or active delirium—and then to administer them carefully and discriminatingly, but without fear. Alcohol should not be administered as a matter of routine. It was usually indicated in drunkards and in old persons, but in the robust and strong it should be given only when the pulse was losing in strength or increasing in rapidity. Few such cases with a pulse rate below 110 required alcohol. Digitalis was undoubtedly losing ground as a cardiac tonic, while caffeine was gaining in favor. Strychnine was generally admitted to be the most useful heart tonic in pneumonia. The specific plan of treatment by drugs believed to be inimical to the life of the pneumococcus had not gained much headway during the year. Several reports of their successful use had accrued, but these had dealt with a very small number of cases, and had not done much to advance the method. Regarding the use of antipneumotoxin, the literature of the year showed a surprising inactivity, especially among the French and Germans. The chief work in this field had been done in our own country. Some very encouraging and instructive accounts of the use both of cultures of the pneumococcus and of animal serum were found in contemporaneous periodical literature. We were still faced, however, with the continued inability of the experimenters to elaborate an antitoxin possessing a uniform and stable constitution. Until this stumbling-block was surmounted, progress in this department would be slow and uncertain.

Dr. Bridges, of Ogdensburg, declared his disbelief in the microbic theory of the origin of pneumonia, though admitting that, under certain conditions, it was a septic disease, manifesting itself even in epidemic form. He insisted that the free admission of fresh air to the sick-room of the pneumonia patient was a most important factor in the treatment. He would use morphine when there was much restlessness or sleeplessness, or for threatened heart failure. Strychnine, morphine, and alcohol were the most useful remedies in this disease.

Congenital Dislocation of the Shoulder.—Dr. Daniel W. Marston, of New York, read this paper and reported cases. He was of the opinion that this

condition arose either from traumatism at birth or in utero or from tuberculosis or osteomyelitis. The majority of cases could be traced to a difficult delivery. The aim of treatment should be to reduce the deformity and secure a useful joint. The treatment should be both mechanical and operative. Manual reduction should be attempted in each patient under three years of age, but failing in this, operative intervention was demanded. It was of the utmost importance to differentiate between congenital dislocation of the shoulder and true obstetric paralysis.

The Relation of Appendicitis to Diseases of the Uterine Appendages.—Dr. A. L. Beahan, of Canandaigua, read a paper with this title. He cited a number of cases in support of the position taken by him. The existence, he said, of febrile disturbance during menstruation, with a swollen, tender appendix, often associated with a constipation and gas formation in the bowel, painful and retarded menstruation, pain in the appendical region, loss of flesh, nervous irritability, and exhaustion made it probable that there was disease of the appendix, and the removal of the appendix became imperative. The full-fledged attack of appendicitis should not be allowed to occur, but should be anticipated by the radical operation.

Small Hospitals and their Administration.—Dr. Louis Nott Lanehart, of Hempstead, gave a brief outline of his views on this subject.

The Necessity of Greater Conservatism in the Use of Vaso-Dilators in Certain Cases of Cardio-Vascular Disease.—Dr. Louis Faugères Bishop read this paper. He said that every form of treatment was much discussed when first used, but later became a matter of form. The nitrites represented a great advance in therapeutics, but had become too much a routine treatment, being often given in so small a dose as to be inert or in such large dosage as to be injurious. In the use of these drugs every case must be a physiological study. Accessory hygienic measures must be employed in the greatest degree to keep down the blood tension. The actual effect of digitalis must be determined by experiment in all these cases. Used in excess, the nitrites caused dilatation of the heart with paralysis of inhibition. Under proper management patients with myocarditis, nephritis, or vascular disease might attain a condition of comparative health and enjoy it for a definite period of time.

What is Rodent Ulcer?—Dr. J. A. Fordyce, of New York City, read a paper with this title, and showed a number of photographs illustrating the clinical as well as the histological features of this affection. He referred to the differential diagnosis of late syphilitic ulceration of the skin, lupus vulgaris (tuberculosis cutis), and the disease in question. He stated that mistakes in diagnosis not infrequently came under his observation. These mistakes in diagnosis were more frequently made in the late stages of this type of cutaneous cancer when it sometimes lost its pearly-gray, ridge-like margin and appeared only as a more or less extensive ulcer. The age at which it began also led to mistaken ideas as to its nature, for although in the majority of cases it made its first appearance near the age of forty, it not infrequently began much earlier in life. The writer had seen it begin about the age of twenty, and Hutchinson had reported a case in which it appeared when the patient was fourteen. Rodent ulcer differed from other types of cutaneous cancer in its apparently insignificant early stage, in its excessively slow course, and in the absence of little new growth. The ulceration kept pace with or exceeded the newly formed tissue, and thus justified the clinical name with which it had so long been identified. While possessing little power to infect the general economy, rodent ulcer, when well established, showed a remarkable tendency to recur after removal, whether the interference was by surgical or the so-called dermatological methods. That the lymph nodes were not always spared was shown by a case that the writer had observed, in which the lymph node over the mastoid had been infected by a rodent ulcer behind the ear. The patient had also been afflicted with a rodent ulcer in the typical location, *i.e.*, on the side of the nose extending to the inner canthus.

Recto-Colonic Enteroliths and Concretions.—Dr. Samuel G. Gant, of New York City, read this paper. Of the fifty-three cases that he had collected, the enteroliths had been located in the rectum in thirty-four cases. They occurred more frequently in women than in men, and in persons past the age of forty. Balls of hair were frequently found in animals that were accustomed to lick themselves, but similar concretions were not unknown in the human subject. Hair balls had been found in the rectum as a result of rupture of a dermoid cyst. Oat-stones were sometimes found in persons who ate large quantities of oatmeal. They were located more often in the colon and rectum than in the small intestine. They were composed, for the most part, of mineral substances.

Esophoria or Latent Squint.—Dr. Francis Valk read this paper. He did not believe in the old theory of Donders, that hypermetropia was the cause of convergent, nor that myopia was the cause of divergent squint, as there were so many cases that would disprove this theory; nor did he accept the innervation theory of Hansen Grut. His own opinions were based on the so-called muscular theory, associated with the fusion force of the eye. He believed in the power of the straight muscles of the eyes, as shown by their insertion, size, and weight, in which one muscle must show a certain power to act under the stimulation of the fusion force, and that this power should bear a certain relation or ratio to the action of the other muscles. This power was shown by the prism test, an old and reliable one, and, in the writer's opinion, the only one that could be depended upon properly to indicate the true balance of power in these muscles or the want of power, as an imbalance, and the probable muscles that were at fault; while all other tests could be used only or depended upon simply as confirmatory tests. In the relation of these muscles, one to the other, he expected the abduction, as compared to adduction, to be as one to three or four, and that outside of these limits we might have latent squints. He accepted this ratio as a standard. After testing the muscles by this method there was frequently homonymous diplopia with the red glass before one eye, a condition that indicated the advisability of an operation. The writer then gave short histories of sixteen patients showing latent convergent squint by the prism test, who had been operated upon with success. The operation was then described. It consisted in a shortening of the external rectus by a "tuck" with catgut suture, the latter being inserted while the muscle was held by the twin strabismus hooks devised by himself. The catgut was allowed to be absorbed, and the reaction, if any, was very slight.

Demonstration of the Ophthalmophacometer, with Simple Formulæ Relating to its Use.—Dr. Lucien Howe, of Buffalo, gave this demonstration. This instrument, he said, was used for demonstrating the images formed by reflections from the cornea and lens. Generally speaking there were three images, viz., (1) from the cornea; (2) from the anterior surface of the lens; and (3) from the posterior surface of the lens, but it was possible to demonstrate as many as seven such images or reflections. In addition to demonstrating the action of this instrument, the first of its kind in this country, Dr. Howe pointed out some of its practical applications.

Can Interstitial Keratitis be Prevented in the Offspring of Syphilitic Parents?—Dr. Peter A. Callan, of New York, read a paper with this title. He said that this form of keratitis occurred in the growing period. Rarely was there a longer interval than ten months before the second eye became inflamed. Interstitial keratitis, due to acquired syphilis, was very rare. The offspring of syphilitics showed the inherited taint in a small percentage of cases only, if those dying before the age of five years were excepted. The author's conclusion was that physicians could delay, but could not wholly prevent the outbreak of interstitial keratitis in a certain number of cases.

Relations between Certain Diseases of the Skin and the Menstrual Function.—Dr. L. Duncan Bulkley, of New York, read a paper with this title. He accepted the view that a woman in her full sexual vigor seemed to pass through a series of psychical changes, in each of which the menstrual period was the climax. Dr. Mary Putnam Jacobi had shown that the excretion of urea was increased during the menstrual flow, and that there was a rise of the body temperature to 99° F. He had records of forty-two cases exhibiting striking cutaneous manifestations in relation to menstruation. Acne was the most frequent skin affection noticed in this connection. In a series of five hundred and ten cases of acne analyzed by him some years ago, he had found it recorded that in one hundred and forty-five, or nearly one-third, there was a relation between the acne and the menstrual flow. In seventy-nine of the cases the acne had been aggravated before the menses, and in fourteen it had been worse after the flow. Some years ago, in a discussion at the New York Academy of Medicine, the late Dr. Peaslee had made the statement that when acne was situated on the chin there was always a relation between it and the menstrual function; and this observation, the speaker said, he had since had an abundant opportunity to confirm.

Dr. A. Jacobi, of New York, said that he had seen a fair number of cases of vicarious menstruation, including cases in which there had been a monthly discharge of blood from varicose ulcerations. He had also observed a similar type of hemorrhage from the ear, and of course a number of cases of periodical epistaxis.

Hysterical Anæsthesia and Analgesia.—Dr. B. C. Loveland, of Syracuse, presented, in this paper, a report of a case occurring in a woman suffering from hysteria major—a rare disorder in this country. Certain deductions were also made concerning the diagnosis of such cases.

Operations for Deformities following Pott's Fracture.—Dr. W. O. Plimpton, of New York, read this paper. He reported six cases in which the operation that he had done had consisted of division of the bone with a chisel at the point of original fracture. Union had been satisfactory and the result uniformly good. Complete excision, he said, was a last resort for extreme cases, usually of long standing, in which milder measures had proved ineffectual.

Dr. Carl Beck, of New York, thought that with the guidance of the Roentgen rays these deformities should not occur; and if they did, the surgeon should, under their guidance, do that operation which seemed to be indicated in the individual case.

Deep Breathing as a Curative and Preventive Measure.—Dr. John H. Pryor, of Buffalo, read a paper on this topic. He spoke of the importance of thorough oxygenation in both men and women as a therapeutic measure, particularly in subacute and chronic pleurisy. The effect on the exudate of free forcible action of the lungs was analogous to that observed when a joint that had been long unused was subjected to motion. Cough was no contraindication to such treatment. The inhalation of medicaments through an inhaler was a valuable adjunct to such treatment.

Dr. J. Riddle Goffe, of New York, spoke of the evils of deficient oxygenation in women, and the advantages of simple gymnastics. His plan was to direct such persons to count off a few steps, making it a point to breathe deeply before and afterward.

Dr. D. H. Goodwillie, of New York, said that alimentation and respiration must go hand-in-hand, and in equal proportion in order to secure good health. He then spoke briefly of the mechanics of respiration and the influence of respiration on the vital organs.

Dr. Styles, of Orleans, regarded going up and down hill after breakfast as an excellent exercise in cases of chlorosis, and to overcome the results of pneumonia.

Dr. H. R. Hopkins remarked that horseback riding was an excellent means of artificially deepening the respiratory movements.

Belladonna versus Scopolia.—Dr. Reynold W. Wilcox, of New York, called attention in this paper to the fact that the last pharmacopœia described these two drugs as having nearly the same composition. This was in line with the results of clinical experience.

Indications and Limitations of the Vaginal Route of Attack in Pelvic Diseases in Women.—Dr. J. Riddle Goffe, of New York, discussed this subject at some length, giving the well-known arguments in favor of this route.

Dr. H. J. Boldt, of New York, said that cancer of the uterus should not always be treated by the vaginal route. The infection of raw surfaces by cancer cells had not yet been proved. For interstitial myomata the abdominal operation was preferable, but the vaginal route could be employed for the submucous variety. Because of the greater width of the operative field by the abdominal route the surgeon was in a better position to deal with tubal disease and other complications.

Dr. Scully, of Rome, said that as hernia was preventable, the liability to this accident was no argument against a particular route.

Dr. A. H. Cordier, of Kansas City, also took the position that it was hard to cope with hemorrhage and with secondary disease if the vaginal route were selected.

Disinfection within and without the Body in Diphtheria.—Dr. M. A. Veeder, of Lyons, read this paper. He advised that the septic sore throat should be treated by the use of local germicides. He warned against the liability of disseminating the disease by frequent examinations, and a neglect to observe certain precautions to prevent infection during the act of coughing.

After-Thoughts on Diphtheria.—Dr. I. N. Love, of New York, in this paper spoke in rather faint praise of antitoxin, his idea being to call attention to the fact that our other methods of treating diphtheria had improved in the past fifteen years, and must needs be, in part at least, responsible for the better results of treatment. The present plan of making the diagnosis by a bacteriological examination led to many cases, formerly known as simple follicular inflammation, being classed as true diphtheria. It would be well, he thought, if these different types of sore throat could be more clearly and practically differentiated.

The Treatment of Persistent Suprapubic Vesical Fistula by Means of Bottini's Operation.—Dr. Willy Meyer, of New York, read this paper, reporting several cases.

The Porro-Cæsarean Operation.—Dr. James H. Glass, of Utica, presented this paper. He stated

that the indications were the following: (1) Sepsis occurring after protracted labor; (2) cancer; (3) large myomata; (4) atresia; (5) ovarian tumors; (6) hemorrhage, and (7) dystocia. In general, the choice of castration in women should be left to the patient herself.

Fatty Degeneration of the Heart.—Dr. Thomas E. Satterthwaite, of New York, read a paper on this subject. He stated that in his experience the terms "weak heart," "myocarditis," and "disease of the coronary arteries" were apt to be misnomers for simple fatty degeneration of the heart. But thanks to Hayem, Sée, Romberg, and Bollinger, the last thirty years' work had so elucidated the pathology of this affection that it was now placed on an intelligible basis. It remained, however, to connect the three degrees of fatty degeneration, described by Bollinger in 1898, with three clinical stages, and this the author of the paper attempted to do in this communication. Six cases with post-mortems illustrated the views advanced. He concluded as follows: "Fatty degeneration of the heart is a common affection, not a disease *sui generis*, but rather a metamorphosis or change attendant on and consecutive to various disorders, and notably compensative in valvular disease. It is caused primarily by fevers, toxæmias, dyscrasias, disorders of nutrition, and mechanical injuries, and occurs in senility and parturition. For practical purposes it is convenient to divide it into early, intermediate, and final stages. In each the prognosis and treatment are different. In the early stage, the prognosis is best for complete recovery, provided the patient recovers from the primary disease, and a complete recovery may be anticipated, provided the heart complication is duly considered and treated. For this stage the first requirement is rest, often rest in bed, with such tonics and nutrients as are best suited for the convalescence from acute diseases. In the intermediate stage, while we hardly hope altogether to dissipate the fatty deposit, we should expect so to reduce it in bulk that the muscular substance of the heart will recover enough of its normal tonicity to functionate physiologically. It is in this stage that carbonated baths and resistant exercises, and a well-regulated diet achieve very brilliant results. In the final stage, when there is secondary implication of internal viscera, the prognosis is always unfavorable, for though, thanks to an intelligent use of modern therapeutic agencies and methods, patients will sometimes recover after attacks of suppression, ascites, and cerebral effusion, such instances are rare exceptions to the general rule."

Recent Experiences with Erythromelalgia.—Dr. Henry L. Elsner, of Syracuse, read this paper, referring to a case that he had presented to this society in 1897. The case reported was of interest, because associated with Raynaud's disease—a combination that Dr. S. Weir Mitchell had declared to be impossible. The speaker also referred to another case in which he had seen erythromelalgia associated with syphilitic endarteritis obliterans. He was of the opinion that the disease depended more upon arterial than upon nervous disease.

Results following the Cure of Chronic Defects in the Vesical Function.—Dr. Eugene Fuller, of New York, read a paper with this title. The author said that while a normal bladder emptied itself completely at the end of each urinary act, there were numerous factors which, if existing, served to cripple that function, and such crippling long established produced certain pathological changes in connection with the urinary tract. His article was to illustrate the fact that, when such factors were surgically removed, the tendency to repair these pathological changes manifested itself strongly. Among these factors were stricture, chronic contraction of the prostatic fibres encircling the vesical neck, senile prostatic hypertrophy, calculi, and tumors. The direct causes for these conditions were vesical tenesmus, stagnation of urine, and urinary infection. Vesical tenesmus, long continued against a slowly increasing obstruction to urination, caused hypertrophy of the muscular fibres of the bladder wall to such an extent that in extreme instances it became thickened somewhat over half an inch. Such bladder walls were firm and unyielding, their cavities contracted, and their capacities small. Stagnation caused vesical distention and stretching of the bladder walls, sometimes even rupture ensuing. An atonic bladder was one that had been greatly overstretched, thereby losing its contractile power. The factor crippling the vesical function generally developed slowly, the gradual increase of vesical muscular hyperplasia for some time keeping pace with the increasing obstruction, but at last, the obstruction getting too great, dilatation of the cavity and stretching of the walls began. The author described the appearance of such a cavity as trabeculated and rugous, in some instances deep sacculi forming. Not alone the bladder walls, but also the ureters and renal pelves showed the effects of chronic vesical stagnation, the uretero-vesical valves becoming in extreme instances so patulous that the tip of the little finger could pass them without resistance; and the natural ureteral resistance to a vesical reflux being removed, the result was the development of an intra-pelvic fluid pressure and the establishment of hydronephrosis. When the hydronephrosis was extensive, the kidney was involved by this stretching process, and its function was finally crippled to a large degree. Vesical infection added the inflammatory element to the above processes; the infective process first manifesting itself by the development of a cystitis. However, it was the ascent of the inflammation along the patulous ureters and into the renal pelvis which was of chief importance in this connection. Inflammation in the renal pelvis was especially dangerous, because it tended to cripple the renal function by a subsequent direct involvement of the secreting tubules. It was reasonable to suppose that the above pathological effects, especially those of a severe grade, would not immediately disappear after the crippling factor was removed, but it was surprising how soon normal conditions would be effected if the remedial operation had been thoroughly performed and the after-treatment properly attended to. The author emphasized the importance of the surgeon bearing in mind that not only should the disturbing factor be removed, but there should also be vesical rest through artificial drainage until the resulting lesions in connection with the urinary tract had had time to repair.

A Simple and Accurate Method of Substitute Infant Feeding.—Dr. Henry Dwight Chapin read this paper. He said that there were three equally important factors in the preparation of a substitute for woman's milk, viz.: 1st. Selection of good cow's milk; 2d. Modification of the milk with reference to percentages; and 3d. The choice of a diluent. Milk was rendered unfit for use by the growth of certain kinds of bacteria. Such growth was prevented by cooling milk to below 60° F. This also promoted the separation of the cream. If the milk were bottled immediately after milking, the cream would have risen by the time the milk was delivered to families. There was great variation in the richness of milk and cream, but the same milkman's supply was quite uniform from day to day. Calculated mixtures of milk and cream were not accurate and served only to confuse, as standardized milk or cream could seldom be procured. The variation of milk and cream in milk bottles was shown by an illustration of a bottle of milk on which the cream had risen. There

were two great classes of milk: 1st, those that formed hard solid curds with rennet (*e.g.*, cow's and goat's milk), and 2d, those that formed soft, flaky curds with rennet (human milk and that from the mare and ass). Digestive enzymes acted by contact, and the food that was most finely divided and could most easily leave the stomach was the most suitable for weak digestions. The proteids of woman's milk easily left the stomach. When the proteids of cow's milk were diluted with water, only a small quantity would readily leave the stomach. Dilution with a wheat or barley gruel, in which the starch had been digested, broke up the curds. Digested gruel was made by boiling a heaping tablespoonful of flour with a pint of water, cooling, and adding an aqueous solution of diastase. The latter could be made at home from malted barley grains. Specimens of milk, diluted with water and digested wheat gruel, and curded by rennet, were presented. The curds, with the digested gruel diluent, passed through a sieve having nine hundred meshes to the square inch; those with water diluent remained on the sieve. Milk should be bottled and cooled at the dairy. From nine to sixteen ounces of the top milk should be dipped off into a pitcher or bowl. Here the fat and proteids were in about the same ratio as in woman's milk. If a siphon were used the sediment went into the infant's food. The infant's food should be made of one-eighth to one-third of nine ounces of top milk, or of one-eighth to two-thirds of sixteen ounces of top milk, the remainder consisting of digested gruel. One part of sugar should be added to twenty or twenty-five parts of food. Fine adjustments of percentages were not needed by this method. Nearly the same percentage results would be attained with any milk. Rich milk would require to be diluted more and poor milk less. Each additional ounce removed from the milk bottles reduced the fat in the top milk from one-half to one per cent., which cut down the fat in the infant's food one-eighth to one-third, depending on the dilution.

Ectopic Pregnancy; Primary Rupture the Opportune Time for Making Diagnosis.—Dr. George McNaughton, of Brooklyn, read a paper with this title. He said that the missing of a menstrual period associated with pain and discomfort should always suggest the possibility of ectopic pregnancy being present. When rupture occurred, suffering was always very great, and was often associated with uterine hemorrhage.

Leprosy in the Hawaiian Islands.—Dr. Charles E. Davis, of Albany, discussed this subject.

An X-Ray Study of the Causes of Disability following Fractures Involving the Elbow Joint.—Dr. Samuel Lloyd, of New York, presented a communication on this subject. He said that in his experience the ankylosis following injuries to the elbow was always bony. The impairment of function might result from the presence of callus, fragments of displaced bone, or the head of the radius. When a satisfactory reduction could not be effected under anæsthesia he advocated a resort to the primary operation, just as one would for an irreducible compound fracture. If the displaced parts could not be replaced they should be removed. The arm should always be put up in a position of flexion, and passive motion should be instituted about twenty-one days later.

Dr. R. H. M. Dawbarn, of New York, said that when the surgeon did not have an *x*-ray apparatus at hand, the swelling could be reduced and the diagnosis greatly aided by the application of an Esmarch bandage under anæsthesia.

The Tonometer and its Value in Determining Arterial Tension.—Dr. Henry L. K. Shaw, of Albany, described this instrument and its uses.

Pleuro-Pericardial and Diaphragmatic Adhesions.—Dr. D. H. Goodwillie, of New York, read this paper. He called attention to the great frequency of interpleural pathological conditions as compared with other pulmonary diseases, as shown by physical examinations and autopsies. Pleuro-plastic exudation, if not early recognized and removed by appropriate measures, thickened the pleuræ, organized and formed adhesions between the costal and pulmonary pleura, the pericardium, diaphragm, and pleura. These latter complications were of serious importance, and were not so readily recognized by the physical examination. He insisted on the importance of a very careful study and observation of rational and physical signs respecting interpleural pathology, and on the auscultator having perfect hearing and ability to recognize, first, normal chest sounds, and then the abnormal sounds which are in great variety, and dependent upon many pathological conditions. The necessity of a knowledge of the laws of acoustics as applied to the chest sounds, and how they were conveyed and changed by passing through the various tissues from the point of inception within to the ear of the auscultator, was also pointed out. In the year 1876, Dr. Goodwillie said, he had by invitation of the late Dr. Leaming, of New York, examined with the latter the diseases of the chest in his service at St. Luke's Hospital. One hospital case was given in full, and many others from private practice were summarized. The autopsies in all cases verified the diagnosis of pleuro-pericardial and diaphragmatic adhesions. Dr. Goodwillie also exhibited colored wax models showing these lesions. During the summer of 1875, by invitation of the committee of the United States government appointed to investigate bovine pleuro-pneumonia, he, with others, had made an examination of condemned cattle. The autopsies had been immediately performed, and had shown the pathological conditions that had been noted in the human being.

Differential Diagnosis in Diseases of the Spinal Cord.—Dr. Edward D. Fisher, of New York, read this paper. He said that the diagnosis in diseases of the spinal cord was dependent on knowledge of the structure and functions of the different parts of the cord. The anterior horns controlled the nutrition and action of the muscular system. Any destruction of this region must cause paralysis and wasting of the muscles involved. The lateral tracts were essentially motor in function, having no sensory or nutritional influence. Hence disease involving these tracts caused only paralysis without wasting of the muscles; and as cerebral inhibition was cut off, exaggerated reflexes, as seen in lateral sclerosis. The posterior tracts were entirely sensory in function; disease here must cause disturbance in feeling and co-ordination, dependent on sensation, as seen in locomotor ataxia. The principal diseases under these headings were easily classified as follows: 1st. Diseases of the anterior horns, as poliomyelitis acute and chronic, progressive muscular atrophy, and hemorrhages into the cord substance. All these diseases were especially characterized by paralysis with atrophy of the muscles. 2d. Diseases of the lateral or crossed pyramidal tracts, as seen in lateral sclerosis following myelitis, injuries, Pott's disease, etc., in which there was paralysis without atrophy. 3d. Diseases of the posterior columns or tracts, which, being only sensory in function, gave sensory disturbance without paralysis or atrophy, as seen in tabes.

Pus in the Peritoneal Cavity.—Dr. Robert T. Morris, of New York, in this paper dwelt at length upon the phagocytic action of the peritoneal cavity and its ability to deal with pus present there.

The Indications for and Limitations of Spinal Cocainization in Surgery.—Dr. George R. Fowler, of Brooklyn, presented a paper with this title, but owing to lack of time he offered only a brief *résumé* of

what was known of this comparatively new surgical procedure.

Masturbational Neuroses. — Dr. William C. Krauss, of Buffalo, presented a few brief considerations drawn from his experience in this field.

Second Day — Wednesday, January 30th.

Appendicitis.—Dr. John H. Doughty, of Matteawan, presented in this paper some theoretical considerations on appendicitis.

Tendinitis and Tenosynovitis Prolifera Calcarea.—Dr. Carl Beck, of New York, reported a case of this kind, with *x*-ray demonstrations.

The Treatment of Puerperal Fever.—Dr. Herman J. Boldt, of New York, presented this paper (see page 169).

The Early Diagnosis of Insanity.—Dr. Charles F. MacDonald read this paper. He said that the subject was of importance to the general practitioner owing to the fact that, in a vast majority of cases of insanity, the responsibility of recognizing its existence, in the first instance, devolved upon the family physician. Its importance was also attested by the fact that insanity was a disease from which no one could claim exemption, it being in effect more frequent, serious, and far-reaching, and involving a wider range of interests than any other malady known to mankind. There were upward of twenty-two thousand insane in custody in the State of New York today, involving an outlay of $20,000,000 for hospital plants and equipments, and an annual expenditure of $5,000,000 for maintenance, repairs, and improvements. There was no disease which was more likely to be mismanaged in its initial stage than insanity. The study of insanity presented nothing new or incomprehensible. Its phenomena, on the mental side, consisted largely of modifications of the natural characteristics of the individual, whether in the direction of exaggeration, perversion, or diminution of these qualities, the modifications being merely the outward expression or symptom complex of disease or disturbance of the intellectual areas of the brain. These symptoms might be summarized as a prolonged departure from the methods of thinking, feeling, and acting, which were usual to the individual when in mental health. Insanity was a comparative state, there being no common standard of sanity, departure from which constituted insanity. In determining a person's mental condition he must be compared with himself, *i.e.*, with his normal mental status, and not with any other man. Two individuals might exhibit precisely similar mental symptoms, and the one be of sound mind, while the other would be a pronounced lunatic. The stage of invasion might occupy days, weeks, or even months, although in some cases the onset was quite rapid and any marked change in the mental or moral tone of an individual should at once arouse suspicion of approaching insanity. Prominent prodromata of mental disease were disturbances of bodily functions, morbid emotional manifestations, and alterations in the mental characteristics of the individual. Somatic functional disturbances expressed themselves in various ways, such as insomnia, headache, tinnitus, vertigo, vasomotor disturbances, anorexia, indigestion, constipation, etc. Any or all of these symptoms might occur in persons who never became insane, hence while they were frequently observed in the prodromal stage of insanity they were not pathognomonic of that disease. When found, however, they were always significant as danger signals, especially if occurring in persons who were predisposed to mental disease. Insanity was rarely due to a single predisposing or a single exciting cause. Usually a combination of causes would be found if sought for, although the immediate cause of all insanities was a state of malnutrition of the brain. Any disease or condition which impaired the bodily nutrition or altered unfavorably the quality or quantity of the blood supply was capable of becoming a cause of insanity. The functional integrity of the mental faculties depended entirely on the healthful activity of the physical system. There could be no unsoundness of mind, in a medical sense, without unsoundness or disease of body. Many cases of acute insanity could be warded off, if the prodromata were promptly recognized and relieved. Prevention was better than cure, and to recognize mental disorder in its incipiency would frequently enable one to adopt remedial measures at the most opportune time for arresting its progress. Doubtless many minds of the highest order had been damaged beyond repair simply for want of appropriate treatment during the early manifestations of their disturbance.

The Role of the Infections in Women.—Dr. Charles A. L. Reed, of Cincinnati, Ohio, presented a paper with this title. At the outset he insisted that the essential antecedent condition of inflammation of any part of the genital tract was an infection. The normal invasion of the genitalia by micro-organisms was limited to the infra-uterine segment by the epithelium and the peculiar structure of the parts. He held that microscopical examination of the infected secretions was imperative, and that, in many instances, it should be supplemented by inoculation experiments. Infection was controlled by the following laws: (1) The epithelial surface of the genital tract in its integrity was a sufficient barrier to the invasion of the underlying structures by micro-organisms; (2) the normal cervix and its secretions were adequate barriers against invasion of the uterus by pathogenic bacteria that were capable of maintaining a habitat in the vagina; (3) the vagina possessed certain powers of self-disinfection; (4) certain pathogenic bacteria, notably the gonococcus, the Klebs-Loeffler bacillus, and the oïdium albicans, found in the warmth and moisture of the parts favorable conditions for growth; (5) pathogenic bacteria, innocuously present in the genital tract, might become virulent when introduced into the underlying structures by a breach of the epithelium; (6) the pathogenic bacteria, when introduced into previously normal tissues, immediately invoked the process known as inflammation; (7) pathogenic bacteria, not overcome by the leucocytes, might enter the lymphathics, producing secondary phenomena, such as metastases, septicæmia, pyæmia, and even death.

The President's Address—Hernia.—Dr. A. M. Phelps, of New York, presented this address (see page 161).

A Hair Cast of the Stomach; its Successful Removal by Laparotomy.—Dr. Nathan Jacobson, of Syracuse, reported this very rare and interesting case. The patient was a girl of eleven years. According to the history there had been regularly recurring and severe pain in the stomach at night, and frequent vomiting. In April, 1899, a swelling had first been noticed in her abdomen, and the following summer she had begun to suffer from the colicky pains. Physical examination showed the presence of a hard, slightly nodulated tumor, the lower border of which was on a line with the umbilicus. Its long diameter was about six inches. The laparotomy had been done on May 17, 1900. A kidney-shaped tumor had been found within the stomach. The organ was incised, and a black tumor, made up of a mass of hair, was removed. The stomach was sutured in three layers with catgut, and the patient made a good recovery. After the operation she had admitted that from the earliest years of her life she had been in the habit of

biting off the ends of her hair. There had been no return of the gastric symptoms, and the girl had gained in weight and improved in general health. The tumor, which was exhibited, presented a perfect cast of the stomach when in a state of contraction, and weighted fifteen ounces. On section, it had been found to be made up almost entirely of hair. A review of the literature showed that almost without exception the existence of such a foreign body had not been expected, and that in all of the operative cases the patients had recovered, and had been completely relieved of the previous gastric symptoms.

Dr. Robert T. Morris said that in one case of appendicitis he had found a collection of hair within the appendix to have been the exciting cause. The habit of hair-biting was usually a manifestation of a peripheral neurosis. Having lost one case of gastro-enterostomy as a direct result of the giving way of the catgut sutures of the stomach under the digestive action of the gastric juice, he had since feared to make use of catgut sutures when such sutures penetrated to the secreting glands.

Surgery of the Spleen.—Dr. J. Collins Warren, of Boston, Mass., presented a paper on this subject. The more important of the many diseased conditions for which splenectomy had been done were the following: malarial spleen, splenic anæmia, splenic leukæmia, chronic enlargement of the spleen in infancy, hypertrophy with cirrhosis of the liver, atrophic cirrhosis of the liver leading to enlargement of the spleen, amyloid degeneration, echinococcus of the spleen, cavernous angioma, fibroma of the spleen, wandering spleen, twisted pedicle, rupture of the spleen, sarcoma of the spleen, and tuberculosis of the spleen. With the exception of such grave constitutional conditions as splenic anæmia or leukæmia, or amyloid degeneration, splenectomy could not be said to be contraindicated. The author reported four cases.

Dr. Albert Vander Veer, of Albany, described his experience in the surgery of the spleen, which had been, for the most part, discouraging.

Dr. Robert T. Morris called attention to the two prominent dangers in this field, *i.e.*, hemorrhage and shock. The former could be largly avoided by using a saline infusion on commencing to operate, and by being on the watch for prolonged oozing. The shock in these cases was very largely dependent upon the inclusion in the pedicle ligature of the large branches of the abdominal sympathetic. The use of opium and of nitrous oxide as a preliminary to the usual anæsthetic also tended to diminish the tendency to shock.

Inguinal Hernia.—Dr. Melville Ricketts, of Cincinnati, Ohio, read this paper. He said that the term inguinal canal was a misnomer. The proper word should be annulus, for a canal meant a passage-way for fluid. The parts concerned in an operation for inguinal hernia lacked a good nerve and blood supply. All herniotomies should be regarded as modified laparotomies. A statistical study was then presented to show the value of the wire mattress suture and the results of the various methods. The Marcy-Bassini method had been employed in about ninety-five per cent. of all the cases and the wire suture in only about two per cent.

Dr. John A. Wyeth, of New York, said that, to his mind, the essential features in the true method for the radical cure of an inguinal hernia were primarily the entire obliteration of the sac, and secondarily the securing of the proliferation of newly formed and fibrillated connective tissue. As this fibrillation had been shown by laboratory research not to take place to any extent for six weeks, he insisted that his hernia patients remained in bed on their backs for this period after the operation. He objected to the Bassini operation because of the funnel-shaped depression produced in the peritoneum, but added that this could be readily avoided by using Macewen's method of tucking up the sac and suturing it until it was fastened in position permanently by adhesions.

Gastro-Jejunostomy in Gastrectasis.—Dr. A. H. Cordier, of Kansas City, stated in this paper that this operation was useful not only in cases of dilatation of the stomach, but in others, as for example some cases of gastric ulcer. The importance of the operation as a drainage measure had not been sufficiently appreciated.

Dr. A. L. Benedict, of Buffalo, spoke of the value of establishing a jejunal fistula in cases of supposed cancerous or tuberculous disease of the stomach.

Toxin of the Colon Bacillus.—Dr. Victor C. Vaughn, of the University of Michigan, made some remarks on this subject. He said that he had been a warm advocate of the theory that ptomains were the causes of the infectious diseases, but our present knowledge did not afford adequate proof that any ptomain was sufficiently powerful to produce the characteristic symptoms of the disease which was caused by the germ which produced the ptomain. Germs might form the chemical poison within themselves and not by splitting up the soil on which they grew. Some of these germs, and notably the colon bacillus, had very impermeable cell walls. Under ordinary circumstances he was positive that the colon bacillus did not form a poison which would diffuse through its cell wall. Even heating the colon germ in water to a temperature of 356° F. in sealed tubes was not sufficient to break down the cell wall and set free the poison within; hence heating milk containing this bacillus with the idea of sterilizing the milk for food was futile, as this would not destroy the toxin. By a process of artificial digestion, however, the cell wall might be broken down and the poison extracted. Dr. Vaughn exhibited, in the form of an amorphous substance, some of the toxin of the colon bacillus that he had succeeded in isolating by this process of extraction. In reply to a question from Dr. A. Jacobi as to how the colon bacillus set up pathological processes in different organs of the body if its toxin were surrounded by an insoluble membrane, Dr. Vaughn replied that a partial explanation probably lay in the solubility of this toxin in the blood owing to the presence of certain albumins; but it was also likely that while the phagocytes were able to prevent the further growth of the germ, their action in this regard seemed to lead to a setting free of the toxin.

The So-Called Traumatic Neurosis.—Dr. Harold N. Moyer, of Chicago, read this paper, the object of which was to combat the notion that there was such a thing as traumatic neurosis. The back pains of so-called spinal irritation were peripheral and probably represented the effect of the use of muscles in a neurasthenic. They were often indicative also of injury of some of the many joints of the vertebral column.

Officers Elected.—*President*, Dr. Henry L. Elsner, Syracuse; *Vice-President*, Dr. Louis N. Lanehart, Hempstead; *Secretary*, Dr. F. C. Curtis, Albany; *Treasurer*, Dr. O. D. Ball.

A semi-annual scientific meeting will be held in New York City this year.

Septic Intoxication and Traumatic Fever.—As long as the organisms that have gained access to a wound remain limited to the fluids or dead tissues in it, or are purely saprophytic in nature, they are capable of giving rise only to septic intoxication; should, however, any of them be capable of parasitic growth, and they should gain an entrance into the living tissues of the wound, the condition known as traumatic fever arises when the wound is of any size.—Cheyne and Burghard.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, January 14, 1901.

CHARLES N. DOWD, M.D., CHAIRMAN.

Extirpation of the Entire Colon for Hyperplastic Colitis.—DR. HOWARD LILIENTHAL reported this case. The patient, a woman of twenty-one, had been referred to the Mount Sinai Hospital surgical service by Dr. Morris Manges, who had had the patient under observation on the medical service of that hospital. She had suffered for years from frequent foul and mucous discharges from the bowel, and it had finally become necessary to do an inguinal colostomy. This had given only very temporary relief. When seen by him she had had as many as twelve stools a day. Examination of the rectum had disclosed the presence of a number of small polypoid masses. The caput coli was opened through a wound in the right iliac region on December 30, 1899. There was no normal mucous membrane found, the entire mucosa being covered with papillomatous excrescences. One of these had been removed, and on examination by the pathologist had been found to be an enlarged solitary follicle. Everything that could promise relief had been tried, and often with some benefit, but it was evident that the closure of the colostomy wound would again bring back her trouble. Accordingly, the ileum had been divided about four inches from the ileo-cæcal valve, as here it was healthy, and the ileum and lower portion of the sigmoid flexure were then united. This operation had been done early in March. There was much foul discharge from the right iliac wound, and on March 19th the Murphy button had been extracted from the rectum with forceps. By March 26th the number of stools had fallen to about nine a day. On January 15, 1900, the operation for extirpation of the entire colon had been done. The line of anastomosis had been found to be quite perfect. He had cut off the colon at about two inches and a half from the colostomy wound, and had made an effort to evert the stumps of the ileum and colon. The patient had reacted well after this operation, but had developed a pneumonia the next day, apparently as a result of an infection. Dr. Lilienthal said that up to the present time he had been under the impression that this operation was unique, but Dr. Elsberg had just informed him that two such cases had been reported in Langenbeck's *Archiv*, the operation having been done for tuberculous colitis. According to the report of the pathologist the mucous membrane in his case had been unhealthy in every part. It was reported to be a hyperplasia of the solitary lymph follicles.

DR. JAMES P. TUTTLE said that the fecal current had been deflected entirely from the colon in certain cases, and under this enforced rest various new growths had been known to atrophy completely. This operation had been done, even with closure of both ends of the colon, and in one case of this kind that he had himself treated there had been no trouble from this procedure, and the specimen had shown an atrophy of the mucous glands of the colon.

DR. LILIENTHAL replied that it had been utterly impossible to make use of exclusion of the colon in his case because of the very profuse discharge that had been present. He had given the colon a rest of about seven months from the time of the right colostomy. The woman now had two or three well-formed stools daily.

DR. FRED. KAMMERER said that in his experience the colon had been found collapsed so as to be smaller than the small intestine as a result of a few months' rest. The secretion from the excluded colon was very slight. He was disposed to think that a longer period of rest might have accomplished all that was desired without further operation. There were a few cases on record in which total and complete exclusion had been practised without bad results, but such cases were very rare. By complete exclusion he meant one in which not only was exclusion done, but both ends of the colon were closed. He had himself had one such case.

DR. LILIENTHAL said that the woman had not improved after the long rest given, and having in mind the report of the pathologist that malignant degeneration was likely to occur, he had felt justified in extirpating the colon. From inspection of the specimen it was evident that there had been no atrophy of the colon.

A New Operation for Rectal Prolapse.—DR. JAMES P. TUTTLE presented a colored girl of six years in illustration of a new operation for prolapse of the rectum. The operation consisted in making a semicircular incision around the rectum; then dissecting off the rectum thoroughly from the sacrum and scraping the latter free from all fatty tissue. The rectum was then invaginated through the incision and dragged down. Silkworm-gut sutures were passed half an inch apart through the muscular wall of the gut and were then carried up through the opening between the rectum and sacrum. A purse-string suture was introduced temporarily, but the tendon sutures were left undisturbed afterward. He had first done this operation four years ago, and had performed it altogether in ten cases.

Colloid Cancer of the Rectum.—Dr. Tuttle also presented a man twenty-three years old, who had had undoubted cancer of the rectum and sigmoid. Last June he had operated, taking out almost the entire sigmoid after a preliminary colotomy. The colotomy wound had been closed in August. This was the only patient with colloid cancer of the rectum whom he had ever seen live for any length of time after the diagnosis had been made. It was an uncomplicated case of resection of the rectum.

Typhoid Perforation of the Bowel; Successful Operation.—DR. A. A. BERG presented a boy of seven years who had been admitted to the Mount Sinai Hospital early last September. According to the mother, he had been comparatively well until the night before and had been going around, but close questioning had revealed the fact that he had had some headache. The day before admission he had been seized with pain in the right iliac fossa and with vomiting. The bowels had moved naturally, and there had been no collapse up to that time. During the day the pain had extended and had become more severe, and with this there had been a rise of temperature. He had entered with a diagnosis of acute perforative appendicitis. When seen by the speaker about ten o'clock that evening there had been present a diffuse peritonitis, a pulse of 135, and a temperature of 103° F. There were no eruption and no enlargement of the spleen, but some fluid was present in the abdomen. The peritonitis was suspected to be of appendicular origin, and an operation was immediately undertaken. When the abdomen was opened a diffuse purulent exudate was revealed, and the appendix, though congested, presented nothing unusual when excised. The peritoneal glands were noticed to be of unusual size. The whole length of the small intestine had then been explored, and about its middle was found a small perforation, through which the intestinal contents were oozing into the peritoneal cavity. This was the only perforation. The intestine was washed with warm water and replaced, and the abdominal wound, with the exception of an opening for a very small wick drain, was closed after the perforation in the ileum had been sutured. The child had been in collapse at the close of the

operation, but had responded well to stimulation. The next morning the pulse had been 125 and the temperature 104°. The temperature had continued high for a week. On the fifth day a stitch abscess had been found and drained. On the twentieth and twenty-first days a positive Widal reaction had been obtained by the pathologist.

Traumatic Intestinal Perforation; Operation; Recovery.—Dr. Berg also presented a boy ten years old, who had been admitted to the hospital on November 18, 1900. The evening before admission he had been run over by a coal cart. There was severe abdominal pain without vomiting. The urine was passed normally. He had been admitted about twenty-five hours after the accident. At that time the abdomen had been tympanitic and rigid, and there had been absolute obliteration of hepatic and splenic dulness. Evidently there had been a rupture of the intestine with escape of gas and intestinal contents into the peritoneal cavity. An operation had been done immediately. After an incision had been made into the abdomen in the median line the colon was found moderately injected and distended. There was some sero-purulent fluid in the free peritoneal cavity. Systematic exploration of the intestine had been undertaken, beginning at the highest part. A rupture had been found at the junction of the duodenum and jejunum. It was three-fourths of an inch in length and extended about half an inch into the mesentery. From this opening was escaping a small quantity of bile-stained coagulated albumin. A Czerny suture was at once passed through the mucosa at the site of rupture, being inserted parallel to the transverse axis of the intestine. It was impossible to pass the suture at a right angle to the transverse axis nor was resection possible, because the rupture was practically at the junction of the duodenum and jejunum. Two layers of continuous Lembert suture were placed over the first suture. No other rupture was found. The intestine was washed with warm water and replaced, and the abdomen was closed with the exception of an opening for a small iodoform-gauze drain. The operation had occupied about forty-five minutes, and the boy had been in collapse at its completion. He had, however, responded well to stimulation and the next day had had a pulse of 116 and a temperature of 101°. The bowels had moved on the following day. The boy had done exceedingly well up to November 28th, or ten days after operation, when an infection of the stitch holes had occurred. At this time vomiting had set in, and his general condition had suddenly become much worse. Under nitrous-oxide anæsthesia a second laparotomy had been done, and this had revealed a plastic peritonitis around the edge of the wound, and further search had shown an intestinal obstruction produced by a band of adhesion formed around the gauze drain. This had been cut, and from that time on the boy had done well. The wound was now almost healed.

Dr. C. N. Dowd asked on what grounds the diagnosis of typhoid fever had been made. He did this because typhoid perforation in the second week in an ambulatory case was rather unusual, as was also the site of the perforation.

Dr. Berg replied that the perforation had been situated immediately in the centre of a swollen Peyer's patch. Examinations had been made daily for the Widal reaction, but this had not been obtained until the third week, and then it had been positive even with a dilution of one in forty. According to the literature, ambulatory cases were rather prone to this accident.

Fissure of the Head of the Radius.—Dr. Carl Beck presented a case of fissure of the head of the radius occurring in a young woman. He pointed out that fracture of the head of this bone without displacement was always very difficult to diagnose, and hence it was evident that fissure of this part could not be made out without an *x*-ray photograph. The injury in the present case had been caused by falling downstairs and striking the arm against a piece of stone. There had been much ecchymosis, leading to the suspicion of fracture, but when the patient was seen by him two days later it had been impossible to detect a fracture by the usual physical examination. The *x*-ray photograph had, however, cleared up the diagnosis. After four weeks another skiagraph had been taken. The function of the part had not been restored, apparently because of an effusion into the joint. Even now, three months after the injury, the function was far from perfect.

Post-Diphtheritic Laryngeal Stenosis.—Dr. John Rodgers presented a little girl who had been intubated at the Willard Parker Hospital on May, 1898, and as the tube could not be permanently removed it had been allowed to remain until June, 1899. He had then seen the case at the Gouverneur Hospital, and had treated the child by the insertion of a very large tube. With three changes the tube had been left in until March, 1900. The child had suddenly become asphyxiated in the ward one day, and an impromptu tracheotomy had been demanded, and the high operation had been very hastily done in order to save life. She had done well for about two weeks, and then the dyspnœa had recurred. Intubation having been attempted, it had been found that nothing could pass by the lower end of the thyroid cartilage. A careful tracheotomy had then been done, the stricture dilated from below upward, and a large intubation tube inserted. This had been changed every seven or eight weeks until last November. Since then the tube had been out, and she had done well. The speaker said that very few cases of this post-diphtheritic stenosis had been reported, and its pathology was still obscure, but apparently it was dependent upon a hypertrophy of the intralaryngeal tissue. It could be cured only by the insertion of a very large intubation tube.

Dr. Rodgers also presented a man who had had a chronic stenosis and had been treated first by a high tracheotomy and afterward by forcible intubation.

Dr. Emil Mayer said that in a case of gunshot wound of the larynx in which there had been a comminution of the thyroid cartilage he had encountered unusual difficulty in intubating. He had found that the difficulty lay in the fact that the man choked up very quickly with the ordinary method of performing intubation. To obviate this he had devised a hollow introducing instrument for attachment to Dr. Rodgers' hard-rubber intubation tube. If tracheotomy was to be done in a case in which it was suspected that dilatation would subsequently be required it was absolutely necessary that this operation should be done high up.

The Field of Ethyl-Chloride Narcosis.—Dr. Martin Ware presented a paper on this subject, based upon an experience with it in two hundred cases of minor surgery. The form of ethyl chloride used by him was that known as the monochloride. He had been able to find a record of eleven thousand two hundred and seven cases of narcosis with ethyl chloride. A certain degree of concentration of the ethyl chloride in the gaseous state was necessary. It had been recommended to spray it upon the under surface of the ordinary chloroform mask, covered with oil-silk, but such a method was awkward and wasteful, and he had accordingly soon abandoned it for the ordinary mouthpiece of the nitrous-oxide apparatus. The end ordinarily connected with the gas reservoir was to be closed tightly with a plug of cotton. By proper management of this mask the patient got only pure ethyl chloride and oxygen. It was more satis-

factory and far more economical to imitate the "drop method" by spraying the ethyl chloride intermittently in small quantities. This also had the advantage of preventing the formation of hoar frost on the gauze. The inhalation of ethyl chloride was pleasant, and the intense cold was not observed by the person inhaling it. The average quantity required to produce narcosis was between five and six grams, and there was usually but little excitement except in alcoholics and neurotics. At first the pupils dilated; then they contracted, and if the anæsthetic was pushed too far the pupils again dilated. Strange to say, the light reflex was not abolished. Anæsthesia usually ensued abruptly after one or two minutes. Unless a meal had been taken just before the anæsthesia, there was usually no vomiting. Alcoholics required large quantities of ethyl chloride and were apt to remain very rigid. This anæsthetic, the speaker said, worked better in children, as with it there was no struggling or difficulty in breathing, and the relaxation was good. It was as safe statistically in minor surgery as any of the other narcotics. It was cheaper than its chief competitor, nitrous oxide gas, and required no elaborate apparatus. It had proved efficient for curettage, and as an anæsthetic in obstetric practice.

Dr. Willy Meyer said that since he had discarded petrolic ether and had made use of the molecular solution he had added ethyl chloride to the mixture of chloroform and ether. He had been highly gratified with the results obtained with this mixture when administered by the drop method. He had used it now over two years, and it acted on the theory of the boiling-point of the anæsthetic being adapted to the temperature of the body. If too little was given vomiting might occur; if given too freely, cyanosis might result.

A Useful Preliminary to Ether Anæsthesia.—Dr. James P. Tuttle said that he had found ethyl chloride objectionable from the fact that complete muscular relaxation was not obtained. He had used it in a few cases of minor surgery and regretted to say that one of the worst cases of nausea and vomiting following an anæsthetic that he had ever seen had been with the ethyl chloride. The man had come out of the anæsthesia rapidly and then a most intense nausea had supervened and had remained uncontrollable for about thirty-six hours. He had seen no physiological effects from the drug which seemed to him alarming. In nearly two hundred and fifty cases he had used ethyl chloride as a preliminary to ether anæsthesia. By its use in this way patients could be etherized without struggling or excitement, and he believed in the future this would be found to be the chief field for ethyl chloride. His plan was to spray the ethyl chloride on two layers of gauze stretched over the ordinary Esmarch chloroform mask.

Dr. H. Lilienthal said that he had seen ethyl chloride tried in four hospital cases. Two of them were in adults who took ordinary anæsthetics badly, and in them the ethyl chloride had failed. The other two patients were children, and both had taken the anæsthetic readily and had come out of it promptly, but neither child had been sufficiently relaxed to allow of any very delicate operation being done.

Dr. Ware objected to the use of the open mask, particularly because of the great waste of ethyl chloride and the unnecessary expense thereby incurred.

Papillomata of the Larynx in Children.—The treatment is divided under two heads. (1) If dyspnœa is not marked, rest in bed, absolute rest of larynx; tonics, and locally six-per-cent. solution of salicylic acid in alcohol, with three per cent. resorcin added. (2) Operative, either laryngotomy, or tracheotomy, or intra-laryngeal operations.—Dickerman.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 12, 1900.

Eugene Hodenpyl, M.D., President.

Round-Cell Sarcoma of the Thigh.—Dr. F. R. Bailey presented a tumor of the thigh that had been removed by amputation. The patient, a woman aged twenty-two years, was first seen on July 7, 1900. The family history was entirely negative, as was also the personal history in so far as it had bearing upon the present condition. The patient complained of a feeling of slight stiffness in the right thigh, but physical examination was negative. About one week later a second examination was made. There was no pain or tenderness, but on the outer side of the right thigh there was a scarcely perceptible swelling. From this time the swelling slowly increased; the patient began to complain of a dull aching; there was slight tenderness on deep pressure. About the 1st of September an acute condition set in with heat, redness, and a temperature ranging from 100° to 103° F. At this time the swelling presented every appearance of an abscess. These symptoms subsided in about ten days. There remained no pain, but slight stiffness and swelling. The patient went about as usual. The condition was now about the same as when the patient was first seen. The last of October there was a return of pain and tenderness with a rapid increase in the swelling, but without inflammatory symptoms. An exploratory incision was made on November 3d. On incision of the deep muscles and fascia a semi-fluid transparent substance oozed out. Sections from this were exhibited under the microscopes. They showed the growth to be a sarcoma of the small round-cell variety. On November 15th, a hip-joint amputation was performed by Dr. Mravlag. Flaps were cut as short as possible and apparently through healthy tissue. Slight force, used in attempting to rotate the femur during operation, resulted in its fracture, as seen in the specimen. The upper part of the femur had been sawed longitudinally and showed the condition of the interior. The subsequent history of the patient had been uneventful. The wound was entirely healed with the exception of a small area at the point of insertion of the drainage tube.

Aneurism of the Thoracic Aorta.—Dr. Theodore C. Janeway reported the following case, which had been under his observation in the University Medical College clinic from June, 1900. The patient was a Frenchman forty-one years of age, a glass-blower by occupation, who had been exposed to the fumes of lead. There was a history of probable chancre seventeen years before, without definite secondary symptoms. He had been seen for the first time last July. Three years before this he had been taken with pain in the upper part of the abdomen, and this had been pretty constant since that time, and had slowly increased in intensity. He said the pain had always been worse when he was lying on his back. The abdomen was tender in the epigastrium. Examination of the spine had been negative, and jarring had caused no pain. There was a slight area of dulness in the left hypogastric region, which pulsated very slightly. After two or three examinations the diagnosis of a small abdominal aneurism had been made. There were no thrill and no murmur, and the heart was not enlarged. No signs could be found over the back on repeated examination. There was a slight first and second sound to be heard over the tumor. The man had been admitted to Bellevue Hospital in October. While there he had developed a systolic thrill and murmur over this mass, and also over the heart. He had been found dead in the water-closet one morning. At the autopsy a large quantity of blood had been

taken from the left pleural cavity, and an aneurism, apparently of the abdominal aorta, found ruptured into it. A careful examination of the specimen in the laboratory showed that the diaphragm ran down over the tumor mass. Apparently the tendon of the diaphragm made the lowermost portion of the aneurismal sac, and there was no involvement of the cœliac axis by the aneurism, so that it was probable that the aneurism was not of the abdominal aorta. The aneurism seemed to have been given off from the anterior wall of the last portion of the thoracic aorta and grown downward, carrying the tendon of the diaphragm with it. The fact that the aneurism had been held by the tendon of the diaphragm probably explained the very slow increase in size. By dissection through the upper portion of the sac and through the subpleural sac there had resulted a rupture into the pleura. Even at the autopsy the tumor had been taken for an abdominal aneurism.

Horseshoe Kidney.—Dr. A. E. Thayer presented three specimens. The first was a good example of the horseshoe kidney, not discovered during life. The subject was a man of fifty years, who had a varicose ulcer on the right side of the leg. He had died of embolic abscess of the lungs. The specimen weighed 1.3 kgm. and measured, the right, 21 cm. long by 9.75 cm. broad by 7.25 cm. thick; the left, 17 cm. long by 7.5 cm. broad by 5.25 cm. thick. There was a large union of renal tissue at the bases of the kidneys. The pelves were displaced forward. The right renal artery came off low down, close to the junction, and sent a branch to the left kidney. There was one ureter common to both kidneys. There was some parenchymatous nephritis in the left kidney, and in the right were numerous cavities containing a considerable quantity of yellow puriform fluid. There was also a large stone in the pelvis of this kidney.

Interstitial Pancreatitis and Fat Necrosis.—The second specimen had been taken from a German forty-five years of age, who had been in the hospital from October 3d to 26th. There had been a rather obscure train of symptoms, and the diagnosis had rested between abscess of the liver and empyema. There had been no fever and no glycosuria, and very little pain. When the body was opened there had been found general recent peritonitis, and the peritoneal cavity contained about 2,000 c.c. of red purulent fluid. There was gangrene of the lungs. In the abdomen was a large fluctuating mass behind the peritoneum. When this was opened a large quantity of fluid and clotted blood and pus escaped. A small portion of the tail of the pancreas was found wedged in between blood clots. There were areas of fat necrosis over the mesentery. Some of the mesenteric glands were enlarged and cheesy. Microscopical examination showed interstitial pancreatitis and some fat necrosis, but no fat crystals. Smears had been made from the fresh lung, but no tubercle bacilli or other characteristic bacilli had been found. Cultures had also been made, but they had proved negative on ordinary media. By a modified Weigert method a few areas had been found in the tissues which looked a little like a streptothrix invasion. He thought the two conditions were probably coincident.

Arthritis Deformans.—The third specimen was a good illustration of arthritis deformans. The patient had shown multiple dislocations of the joints. The body was extremely emaciated, the total weight post mortem having been about twenty-eight pounds. The patient had been bedridden for twenty-six years. There was firm bony ankylosis of the right hip nearly at a right angle. The stomach showed a number of dark areas surrounded by a hyaline zone—apparently submucous hemorrhages. This woman had developed an acute gonorrhœal conjunctivitis soon after admission to the hospital, and the source of this infection had not been discovered until the autopsy had revealed an enlarged uterus filled with a thick fluid of light green color which contained gonococci.

Dr. James Ewing thought the second case one of very great interest because cases of pulmonary lesions which were not tuberculous and yet resembled tuberculosis were not at all uncommon. He had been fortunate enough to see the cases published by Drs. Larkin and Norris. The particular features of the present case were the lesions in the lungs, the multiple gangrenous foci, and the peculiar caseous character of the lesions in the peritoneum and in the neighboring lymph nodes. When stained, they had failed to show tubercle bacilli, and cultures had also been negative. There had been since then one other probable case of streptothrix pneumonia, but no positive results had been obtained from cultures.

A Method of Obtaining Blood for Chemical Examination.—Dr. J. S. Thacher made some remarks on this subject. He said that his object was to facilitate the making of routine chemical clinical examinations of the blood. He had made use of a flask having a tubule at the bottom ground to fit an aspirator needle. A bandage was tied around the upper arm to congest the veins at the bend of the elbow. The skin was disinfected, and then the needle attached to this flask was plunged into the vein, care being taken not to allow the needle completely to traverse the vein. Two ounces of blood were enough for a urea determination, and this quantity could be readily obtained with but little discomfort to the patient and almost no inconvenience to the physician. The suction was made by the use of a rubber mouth-tube attached to the cork in the mouth of the flask. This study of urea in the blood had already proved extremely interesting. It was very important that the needle should be clean and also perfectly smooth, so as not to cause coagulation within the vessel. Dr. Thacher then gave a demonstration upon himself of the method of obtaining samples of blood with this apparatus.

Remarks on Embedding in Clove-Oil Celloidin.—Dr. E. Hodenpyl made some remarks on the use of a solution of celloidin in oil of cloves and ether as recently advocated by E. M. Stepanow (*Zeitschrift für wissenschaftliche Mikroskopie*, October, 1900, pp. 185–191). The advantages claimed for the method were (1) It was quite as simple as the use of the ordinary solution of celloidin in alcohol and ether. (2) Impregnation went on rapidly and was so complete that very thin sections—3 μ—could be made. (3) It was applicable for double embedding in celloidin and paraffin. (4) It was especially useful for the central nervous system. Dr. Hodenpyl was induced to try the method on account of the rapidity with which material could be embedded and cut into sections, and he showed sections under the microscope which had been embedded in the clove-oil celloidin for but two hours, which were quite as thin and which stained quite as well as sections embedded in the ordinary way. The following was the composition of the solution recommended: Celloidin, 1.5 gm.; oil of cloves, 5 c.c.; ether, 20 c.c.; absolute alcohol, 1 c.c. It required about two days to make the solution. When finished it was of a lemon-yellow color. The technique of the method was quite simple. The soaking in alcohol and ether was entirely done away with. The specimen could be put directly into the solution of celloidin, from strong alcohol, and after it had remained there two hours or more it could be blocked, hardened partially in the air, and finally in eighty per cent. alcohol. A much quicker way was to immerse the block in pure chloroform; or, after embedding in celloidin, the specimen could be dropped in benzol for a short time and then a frozen section made.

Very much thinner sections could be made if the specimen were first soaked for half an hour in oil of cloves, and then embedded in the clove-oil celloidin.

The Use of the Aqueous Extract of the Suprarenal Capsule as a Hæmostatic.—Dr. W. H. Bates exhibited a preparation of the active principle of the gland of the strength of one part in ten thousand. He also showed three or four other alkaloidal preparations. He said that the aqueous extract of the suprarenal gland was the most powerful known hæmostatic. The effect depended much upon the preparation employed. One part of the dried gland should be mixed with ten parts of water in the form of an emulsion. When prepared immediately before use, this emulsion was decidedly active, but it might lose its efficacy in a few hours. An alkaloid had been obtained from the suprarenal extract by Takamini, which he had named adrenaline. Its keeping qualities were good when sterilized and protected from the air. In controlling hemorrhage from the lungs, stomach, bladder, or other organs, the dried, powdered gland was efficient; tablets were less efficient because the excipient interfered with its action. The extract must be brought in contact with the vessels, and a bloodless operation could be done by frequently repeated applications of the extract. Operations on the skin had been made bloodless by the hypodermic use of the extract. Pain neutralized the effect of the suprarenal extract almost immediately. It seemed to be a specific in hæmophilia. The extract had been used successfully in connection with packing of the uterus to control post-partum hemorrhage. Hæmoptysis could be controlled by directing the patient to chew five to ten grains of the suprarenal extract, and swallow it without water at short intervals. The speaker drew the following conclusions: (1) suprarenal extract was the most powerful hæmostatic known; (2) hemorrhage from mucous membranes could be always controlled by its use, and (3) when it controlled hemorrhage, locally or by internal administration, it did so in less than one minute.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ROYAL COMMISSION ON POISON IN BEER—PRIMARY OVARIAN PREGNANCY — PLAGUE—METRIC SYSTEM — S. COLERIDGE'S ANTI-VIVISECTION MOVE—THE LATE DR. POTTER.

London, January 11, 1901.

Beer and poison still hold the field as topics of the day. Our newspapers supply daily statements; medical journals contain cases and observations, societies discuss the epidemic, and coroners inquire and adjourn. It is impossible to keep pace with the accumulation of interesting facts. The Liverpool Institution has held a full discussion on the epidemic which so closely affects that city. Here the Royal Medical and Chirurgical Society has given an evening to it and adjourned its consideration to the next meeting.

The inquests at Manchester, which, as I told you, were adjourned to the 10th, were duly reopened yesterday, and after some rather extraordinary evidence again adjourned.

This morning it is announced that a royal commission has been appointed to investigate the epidemic, and the terms of the reference include exceptional sickness and death from arsenic in beer or in other articles of food or drink, the way in which arsenic was introduced, and the safeguards against such contamination. The commissioners are Lord Kelvin, Sir W. S. Church, P.R.C.P., Professor Thorpe, Dr. Buchanan, Dr. Whitelegge, Sir W. H. Dyke, and Mr. Cosmo Bonsor.

The Obstetrical Society had the good fortune to signalize its first meeting of the century with a paper which will be historical. It was by Drs. G. P. Anning and H. Littlewood, of Leeds. These gentlemen described a case which seems to prove that primary ovarian pregnancy is an occasional fact. The patient, aged twenty-eight years, had been married eight months and was operated on last August for a ruptured ectopic pregnancy about thirty-six hours after the rupture, which occurred fourteen days after the last menstrual period. About two pints of blood and clots were removed. An ovum the size of a Barcelona nut was found which fitted into a firm envelope composed of laminated clot. There was a rent in the right ovary leading to a cavity containing some blood: into this the ovum and sac exactly fitted. Both tubes were examined and showed no rupture. The patient made a good recovery. The specimen and sections of ovum, sac, and ovarian wall were exhibited.

Mr. Bland Sutton, who until recently doubted the existence of ovarian pregnancy, was constrained to admit that this case proves it. He said that he had lately made a trip to Amsterdam to see for himself the specimens of the case related by Mlle. Tusschenbroek at the International Congress of Obstetrics and Gynæcology. He was satisfied that Mlle. Tusschenbroek had proved her case, and through her kindness he brought back a section of the ovum *in situ* which he now exhibited to the society. This specimen and that of Drs. Anning and Littlewood were incontestable proofs of the existence of ovarian pregnancy. In the light of these new facts, another condition of very special interest, viz., blood-cysts of the ovary, would have to be investigated afresh.

Dr. Galabin said he had long believed in the possibility of primary ovarian as well as abdominal pregnancy, though he had not seen a case of the former, but he had met with one which he thought was really primary abdominal pregnancy.

The president, Mr. Alban Doran, who was previously as sceptical as Mr. Sutton, also accepted this case as proof positive, and said it fitted in with that of Mlle. Tusschenbroek and with one of Patenko's, in which fœtal bones were found in an ovarian cyst.

It seems quite in the fitness of things for the Epidemiological Society to discuss the outbreak of plague at Glasgow. Accordingly, at the last quarterly meeting (on the 14th ult.) Dr. A. K. Chalmers read a paper in which many of the facts were set in order. How the first case was contracted is still a mystery. The first man was a docker employed only on coasting vessels, and he took it from his wife, who sickened simultaneously with her infant, whom she carried with her when hawking fish. There were some other cases the origin of which could not be traced. The men employed in disinfecting all had doses of Yersin's serum and none suffered; but the wife of one who lived at a distance and had no contact with other patients was attacked. It is suggested that her husband carried the infection in his hair, as all the men wore overalls when at work.

As it has been shown by Dr. Rosenau of Washington, that plague bacilli retain their virulence for forty-eight days in fabrics kept in the dark at 20° to 23° C., it may perhaps be conjectured that they might do so in the holds of ships, and as the cases at Glasgow were remarkably mild, according to the testimony of those who have seen the disease in other countries, it may well be that some intervening ones were so slight as to escape recognition, or even not to lead the person to seek medical aid.

The part played by animals was alluded to by several. Dr. Chalmers said it might be merely a coincidence, but the old black rat of this country disappeared before the irruption of the brown rat about the time when plague died out.

Dr. Payne said that when plague reappeared in any country it always did so in several places simultaneously. He also said the existence of the bacillus as a saprophyte was undoubted.

Dr. F. Tidswell contrasted the personal contagion, which was so marked in Glasgow, with the activity of rats observed in Sidney. There the rats died by thousands, and six out of fifteen caught on one wharf yielded plague bacilli, as proved by cultures and inoculations. The rats were attacked first, their dead bodies being found before any human beings were attacked. He believed that fleas were intermediaries; for though he had failed to infect by them animals under natural conditions, he had done so by inoculating an emulsion of fleas and found the bacilli in their bodies.

Dr. Willoughby asked if the Australian rats were the same as those of China or India. It might be some were dangerous, others harmless, as in the case of mosquitos.

Dr. P. Manson (president) said he believed in rats and in fleas also. There were many species of rats. One the musk-rat, was said to be immune. The Chinese illogically hold a dead rat a protection against plague, and he had heard of a native and his guests being attacked after dining on rats dead of plague.

The extension of the metric system is not viewed with satisfaction by all. Quite a number of persons regret its alternative introduction to the new pharmacopœia. Some are strong advocates of our duodecimal weights and measures; among them Brigade-Surgeon Lieutenant-Colonel E. Nicholson is a doughty champion of our British system,

which he defended last month in a paper read before the Liverpool Institution. He traces our system to the Egyptian cubit through the Alexandrian talent and the Roman *libra*. He said the decimal system was vigorously pushed by persons who were in reality ignorant of the subject, and warned his hearers against the plausible use of the word scientific. He said the metric system was disliked in France after a century's use, and was evaded as much as possible.

The challenge thus made was accepted by Dr. Grossman, who expressed exactly opposite views. He admitted that the Egyptians had done many things we should not attempt; some that we cannot even explain. Still, their method of weighing and measuring was far less suited to modern requirements than the decimal system, the adoption of which would relieve the brains of the children and facilitate international trade. He considered our cumbrous system only fit for a museum beside the cubit and other relics of antiquity.

Mr. Stephen Coleridge, the advocate of the Anti-vivisection Society has made another move. He has circulated, in a portentous envelope nine by eleven inches, a pamphlet of twelve pages of tables to show which hospitals have any connection with vivisection or any one on the staff licensed under the act. This he calls "a guide for the charitable in the disposition of their gifts and bequests." His object clearly is to gratify his clients by injuring the principal hospitals. As he has favored me with a copy, I have referred to some items and find he has included hospitals as to which he is obliged to admit that the licensed vivisector is no longer on the staff. This, then, is not the case of an error, but of something near akin to deliberate misrepresentation. If Mr. Coleridge thinks his profession privileged in defending a prisoner, he might distinguish such a case from one in which an attack is made on the opinions and action of others. Yet he has ventured to introduce the name of God as a preface to such slanders as these words express.

"These torturers of wretched dogs call themselves physiologists and defend their doings under the traduced name of science. . . . All experience teaches us that it is cowards who are cruel and the truly brave who are merciful."

I wonder if Mr. Coleridge thinks himself brave in making this attack.

The death of Dr. J. B. Potter was referred to by the president of the Obstetrical Society at its last meeting. Dr. Potter was obstetric physician to the Westminster Hospital and a past president; also for many years treasurer of the society. A vote of condolence with his widow was unanimously passed. Dr. Potter held a number of other honorable positions to which he was elected by his brethren, who had the utmost confidence in his trustworthiness and skill. He was an able obstetrician whose aid in difficulties was most welcome, an upright man whose example was a power for good.

LETTER FROM NEW ZEALAND.

(From our Special Correspondent.)

DEGENERACY IN NEW ZEALAND — PREVAILING DISEASES — TAKERS OF QUACK MEDICINES.

AUCKLAND, December 25, 1900.

THE question, What is the preponderating influence, heredity or environment? seems to be one for the solution of which facts are rapidly accumulating. In old and stationary communities, in which from generation to generation people live in the same place, on the same food, and follow the same occupations, the influence of heredity seems overwhelming. But take those people away from their environments, give them a somewhat different climate, but one not so different as to kill them off; give them different food and different or even the same occupations, and mark the change in even one generation. I have seen the feeble indolent Hindu, who was incapable of anything but the lightest form of manual labor, but who could keep on at that for fourteen hours a day when fed on rice and ghee, become a meat eater, and in a few years quite able to do hard work in the sun, and far more reliable, because more steady, than the robust and muscular negro. The change from the slow and stolid Anglo-Saxon—industrious, patient, and persevering—to the quicker-witted but indolent New Zealander, working only eight hours a day, with a day and a half of holiday every week, besides about fifteen other whole-day holidays during the year, his or her teeth decaying almost as soon as they are formed, and generally replaced (in the towns) by at least one jawful of artificial teeth before twenty-five—excessively fond of seeing sports, of betting and gambling, temperate in drink, but smoking to excess, and eating butcher's meat and drinking tea at every meal, is a most remarkable one. It is quite easy to distinguish "natives," as they delight in calling themselves, at a glance.

We who belong to the older generation do not think the change an improvement. Notwithstanding (or because of?) the exceedingly nutritious dietary, only a very small minority, perhaps one in twenty of the mothers, can suckle their children, and as wetnurses are unknown, the children are brought up on artificial foods. As you see the young women pass along the street, it is quite evident to the eye of an experienced medical practitioner that not more than five per cent. are fitted for maternity. Medical practice teaches the same conclusion. The young women suffer from dysmenorrhœa, chlorosis, menstrual irregularities, dyspepsia, headaches, neurasthenia, want of appetite, and whenever they are examined per vaginam prove to have more or less prolapsus with ante- or retroflexion of the cervix. Most of these evils are the direct effect of tight lacing, which is just as prevalent now as it was fifty years ago. How is it that these young women, who have been educated in a way that their grandmothers never were, are as ignorant of the commonest facts of the anatomy of their own frames as ever their grandmothers were?

I should say that a celibate life on the part of the men, and that, coupled with tight lacing, "preventive measures," and factory occupation instead of domestic or outdoor work in the women, are producing a rapid degeneration of the British population in New Zealand which will have the most serious consequences in another generation or two. The excessive use of tea and meat, and, on the part of the men, of tobacco, with tight lacing in the women, ought to be lectured against in every public school. But, then, our school teachers are nearly all such poor creatures themselves!

The plague seems to have entirely died out in Australasia. We in New Zealand have had only two or three very doubtful cases. We have had no epidemic, except influenza, for years past, worth calling an epidemic. And yet people will send their sons to be doctors! The people here are splendid customers for quack medicines, and I should think nine-tenths of the latter come from the United States.

LETTER FROM CONSTANTINOPLE.

(From Our Special Correspondent.)

THE IMPERIAL SOCIETY OF MEDICINE—DEATH OF DR. OTHAN VITALIS — QUARANTINE AGAINST SMYRNA — WAR AGAINST SACCHARIN.

CONSTANTINOPLE, January 6, 1901.

SINCE the jubilee of the twenty-fifth year of the Sultan's accession to the throne there has been little doing in the medical world of Constantinople. The public health has been unusually good, in spite of the dampness and varying temperature which have characterized the autumn and early winter seasons.

The Imperial Society of Medicine has resumed its regular work. It must be admitted that the séances and discussions have been somewhat stale and trivial—worn-out subjects of hygiene, disinfection, poisoning of rats by carbon-dioxide gas, spitting in public as a mode of spreading consumption, reports of individual treatment, etc., which, sad to say, are reported in the local newspapers—an undignified proceeding anywhere, but doubly so in a place like Constantinople. This society apparently does not, at present, take itself seriously.

The Imperial Society of Medicine is another of the institutions founded in the reign of Sultan Ab-dul Medjid. Having imperial support it became, at that time and for many years afterward, an important factor in improving the sanitary conditions of the empire. It had many able foreign members of most nationalities, and the reports and discussions of those bygone days, published in the society's journal, may even now be read with pleasure and profit. It really was a national consultative body on all matters relating to quarantine, epidemics, disinfection, especially in plague and cholera. Many of its members sat on the international health congresses, and greatly contributed to the results arrived at. Dickson, Millingen, Sarell, Müllig, Zaenhaco, Funel, Paspati, Mungeri, Malie were all men of high attainments who gave tone and dignity to the discussions—*quantum mutaties ab ille!* The discussions now are rather subjects of newspaper *réclame* than of real scientific work. Whether from lack of imperial support or becoming overshadowed by the improved School of Medicine, it has ceased to be the thing it was. It may, however, after Eastern fashion, have a revival.

Dr. Othan Vitalis, sanitary inspector and member of the Ottoman health board, died a short time ago. He was greatly respected by his colleagues of the board, and was generally esteemed by the various nationalities here. An incident of some importance has occurred with reference to the appointment of a successor.

The health board, consisting of international delegates (assuming their right of appointing their executive officer),

nominated Dr. Duca, their delegate on the Egyptian health board at Alexandria, to the vacant post. The Sultan, however, did not confirm the nomination of Dr. Duca, but by imperial *iradé* appointed a certain Namyk Bey, an employee of the custom house—not a medical man. This the council resented and declined to recognize the appointment. Here was an old question revived, *i.e.*, is the health board an Ottoman or an international institution? It is variously known as "L'Intendance Sanitaire de l'Empire Ottomane," Ottoman Health Board, and International Sanitary Council. It is generally considered an Ottoman institution, in which European delegates have a place.

The matter has for the moment been tided over. Dr. Vitalis held the double appointment of sanitary inspector and a member of the board. Dr. Zitterer, of the upper Bosphorus sanitary service, has been appointed sanitary inspector without a vote, and Namyk Bey, member of the board with a vote. This, however, is the palace mode of action. The European, or, rather, the international delegates are still recalcitrant, and it is understood have the support of their respective embassies in opposing the pretentions of the palace.

January 4th. Notice of the imposition of ten days' quarantine on arrivals from Smyrna has been issued; comprised between Nova Phocea, included, and Vourla, excluded, dating from January 3d. "This quarantine, with disinfection, of an extremely strict nature will be purged in one of the lazarettoes of the empire." No further information has been vouchsafed. A local paper, however, states that on Friday a man, twenty-one years old, died at the hospital of the Orthodox Community, who had fallen ill at Tomaso. Four persons of his family had already died from a similar malady, which the sanitary inspectors considered a pneumonic influenza.

From the Turkish paper *Servet* of January 5th, however, it would appear that "plague had exerted its ravages twenty days before it was discovered, the symptoms being simply pneumonic. During these twenty days there were fourteen cases, of which twelve were fatal. The local authorities are taking the necessary precautions and from Constantinople Prof. Adil Bey was sent, and his analyses prove the existence of *bacille pesteux*. Dr. Nouri Bey, assistant to Dr. Nicolle of the Bacterial Institute, will also go to Smyrna to superintend the prophylactic measures."

A crusade against saccharin has arisen. The medical council, called upon to decide as to the properties of the substance and its influence on the public health, strongly condemns it, enumerating its dangers from prolonged use. This is but one of many of the somewhat dilettante fads of scientific energy which occasionally occur, and all to preserve the public health. Saccharin is generally considered to be a harmless substance. Other more manifest and daily dangers abound and are allowed to pass unnoticed. If a small portion of the *iradés* relating to sanitation, practice of medicine and pharmacy, and analyses of food, had any practical outcome, Turkey in these matters would be in advance of every other country. The ubiquitous microbe would have no chance. Cleansing streets and alleys, flushing drains, and otherwise disposing of grave health nuisances are minor considerations worthy only of municipal legislation, which, however, they imperfecly receive.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 26, 1901:

	Cases.	Deaths.
Tuberculosis	331	185
Typhoid fever	33	12
Scarlet fever	329	22
Measles	110	2
Diphtheria and croup	332	52
Smallpox	11	1

Serum Treatment of Malaria.—The Berlin correspondent of the *London Lancet* says: "An important communication concerning malaria has been made by Dr. Sander, of Berlin, in the *Deutsche medicinische Wochenschrift*. He has received a letter from Dr. Kuhn, chief medical officer to the South African field force, to the effect that he (Dr. Kuhn) had succeeded in curing malaria by injections of serum. The serum is obtained from horses which have contracted the so-called 'sterbe' disease. By injections of this serum, malaria becomes altered from a chronic relapsing disease to an acute one curable in from two to six weeks; immunity is also obtained; after the injection slight fever of a more continued character generally appears, but no local reaction takes place. Fifty natives, immunized by Dr. Kuhn, did not take the disease in the malarial season of that year, while numerous others who had not been immunized fell ill, but were cured by the injection. Dr. Kuhn being on his way home, more detailed information will be received very soon." It is to be hoped that Dr. Kuhn's specific for malaria may really prove to be an effective prophylactic. His countryman, the well-known Dr. Koch, after travelling far and near for the purpose of investigating the etiology of malarial fever and the best modes of treatment, announced with a mighty flourish of trumpets that the disease was undoubtedly due to a species of mosquito, and that the most effectual remedy was quinine. Of course, it must be gratifying to Manson, Ross, Celli, and the other Italian investigators that so great a man as Koch should set the seal of his approval upon their discoveries, but it would have been still more gratifying if the German scientist had given them some of the credit. From a perusal of Koch's conclusions, one, if ignorant, might easily be led to think that to him alone belongs the honor of tracing the cause of malaria. His dictum concerning the value of quinine in the treatment of the malady is still more amusing, that drug having been recognized as the only one for very many years.

The Training of Sight.—Lord Wolseley having lately remarked upon the good sight of the Boers as one cause at least of their good shooting, and having ascribed this good sight to its constant exercise in the open air, Mr. Brudenell Carter has pointed out that it is not merely a question of open air but of the training of the sight upon things that are far off and difficult to see. The defective vision possessed by so many children who have been brought up in towns is not caused by errors of refraction alone, common as these are, but an actual deficiency in acuteness of vision, a lack of development in the nervous structures involved in the act of seeing. "Vision," he says, "like every other nerve function, must be cultivated for the attainment of a high degree of excellence. The visual power of London children is not cultivated by their environment. They see the other side of the street in which they live, and the carts and omnibuses of the thoroughfares. They scarcely ever have the visual attention directed strongly to any object which it is difficult to see or which subtends a visual angle approaching the limits of visibility; and hence the seeing function is never exerted to anything like what should be the extent of its powers. With a country child the case is widely different." Mr. Carter would like to see a place given to excellence of vision among the various physical qualifications which are habitually tested by competition, and for which prizes are awarded, and he urges the desirability of volunteers taking up exercise and training of sight. "It is at least certain that our riflemen would not shoot worse for having learned to see better."—*Hospital.*

The Pygmies of the Great Forest.—A very instructive article on pygmies is contributed by Mr. Lydekker in *Knowledge* for November. This peculiar race of people live in the Upper Congo forest, which is so vast that one may journey through it for weeks without coming to the other end. "In this perpetual gloom live the pygmies, the most diminutive of the human inhabitants of the globe, of whose existence

there have been more or less authentic rumors since the time of Herodotus and Aristotle, but whose true characteristics and mode of life it has been reserved for recent times to disclose. . . . In 1861 Dr. Touchard records the destruction of a tribe of dwarfs, whom he calls Akoa, in the interior of the Gabun; and states that an adult who had been captured measured only four and one-half feet in height and had a comparatively short and rounded head. In still more modern times, when the interior of the Dark Continent was gradually being opened up, Stanley heard of pygmies whom he calls Watwas, in the country within the great bend of the Congo, who hunted the lordly elephant to death with poisoned arrows, and whom he described as of a chocolate-brown color, and a Dr. Wolff refers to the members of the same or an allied tribe as never exceeding four feet seven inches in height, and averaging four inches less. But to the celebrated German traveller, Dr. Schweinfurth, was reserved the honor of first making known to European science the Akeas of the ancient Egyptians, whom he first met with at the court of the ruler of Mambeth, but whose home is on the Aruwimi, a tributary of the Upper Congo in about latitude three degrees north and longitude twenty-five degrees east. It will also be remembered that Dr. Donaldson Smith, while exploring the virgin forest abutting the Amazon and Orinoco, came across a tribe of pygmies who were even smaller in stature than those met with in Africa."

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended January 26, 1901:

		Cases.	Deaths.
Smallpox—United States.			
District of Columbia, Washington	January 12th to 19th	2	
Florida, Jacksonville	January 12th to 19th	7	
Illinois, Cairo	January 5th to 19th	5	
Chicago	January 12th to 19th	12	
Kansas, Wichita	January 12th to 19th	6	
Kentucky, Lexington	January 12th to 19th	2	
Louisville	January 4th to 18th	1	1
Louisiana, New Orleans	January 12th to 19th	7	2
Shreveport	January 12th to 19th	5	
Massachusetts, Lawrence	January 12th to 19th	1	
Minnesota, Minneapolis	January 12th to 19th	11	
St. Paul	January 5th to 12th	8	
Nebraska, Omaha	January 8th to 15th	7	
N. Hampshire, Manchester	January 12th to 19th	39	
New Mexico, Fort Stanton	January 14th	1	
New York, New York	January 12th to 19th	9	5
Utica	January 12th to 19th	1	
Ohio, Cincinnati	January 12th to 18th	3	
Cleveland	January 12th to 19th	57	
Oklahoma, sixteen counties	January 11th	289	
Pennsylvania, Erie	January 12th to 19th	1	
Pittsburg	January 12th to 19th	3	
Tennessee, Memphis	January 12th to 19th	6	
Texas, Houston	January 12th to 19th	44	
Utah, Salt Lake City	January 12th to 19th	32	
Wisconsin, Green Bay	January 12th to 20th	1	
Smallpox—Foreign.			
Belgium, Liege	December 15th to 22d	1	
Brazil, Pernambuco	December 8th to 15th	..	34
Egypt, Alexandria	December 17th to 24th	2	2
England, Leeds	January 5th to 12th	1	
London	December 29th to January 5th	1	
France, Paris	December 29th to January 5th	6	
India, Bombay	December 18th to 25th	..	1
Mexico, Vera Cruz	December 29th to January 5th	..	3
Scotland, Edinburgh	December 29th to January 5th	1	
Glasgow	January 4th to 11th	66	3

*On steamship *Friary*.

Alcohol as an Antiseptic.—Regarding the value of alcohol as a disinfectant, particularly for the hands, Salzwedel and Elsner report the result of experiments made by them in Koch's laboratory. The authors maintain that these researches show that alcohol is of use in preparing the hands for operations, not merely because of its hardening effect on the epidermis, but also as an active antiseptic; in this respect they assign it a potency intermediate between carbolic acid and corrosive sublimate. They recommend that the hands after washing with soap and water be well soaked in eighty-per-cent. acidulated spirit (which is diluted to the proper strength by the water remaining on the hands) before the performance of an operation.—*The Hospital.*

Successful Use of Tuberculin in the Treatment of Lupus Vulgaris.—Dr. Edward F. Maynard reports to the *British Medical Journal* from the Sussex County Hospital, England, a successful case of treatment of lupus of the nose of three years' standing. In October, 1900, the patient had been well ever since discharge from the hospital in the previous August. The nose had given no trouble whatever, there was no evidence of any disease, and considering the extent of the scraping operations and of the tuberculous infiltration as shown by the reaction to the injections there was remarkably little deformity. Whether the cure will be permanent or not remains to be seen, but at all events the considerable amelioration, both as regards suffering and the time given up to successful operations, warrants the retaining of tuberculin among the most useful of anti-lupus remedies.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

SUMMARY OF THE PROGRESS MADE IN THE NINETEENTH CENTURY IN THE STUDY OF THE PROPAGATION OF YELLOW FEVER.[1]

By CHARLES FINLAY, M.D.,

HAVANA, CUBA.

If we cast a retrospective glance over the track of medical opinion during the past century, in matters relating to the propagation of yellow fever, it is curious to observe its wavering course until the last two decades, when a steady advance was set on foot, leading in the end to the glorious truth so recently proclaimed by some distinguished members of this congress.

As far back as 1812, Dr. Bartolomé Colomar, describing the severe epidemic of yellow fever which in 1811 had decimated Murcia as well as other towns in Spain, refers to the limited radius of influence (considering the patient as a centre) which characterizes the virus of yellow fever, the limit being variously estimated at from eight to sixteen yards. He also states that the general belief that the infection was conveyed by immediate contact with the sick, or by stuffs and clothes impregnated with its miasms, was a mistake, as the attacked were mostly those who lived in houses already infected by the presence of another case, even when no intercourse had existed between the inmates; that the mere touching of a patient or visiting him for a few moments, as happened with physicians, did not convey the contagion, the result having proved that they were never attacked unless a case occurred in the vicinity of their own dwellings. On the other hand, when the epidemic was at its worst, many persons took the infection by merely entering the city of Murcia for a few moments, even though they had neither seen nor touched any of the sick or dead. Finally, the author of the old pamphlet, as if forestalling modern ideas about germ diseases, says: "Contagious miasms, like the seed of vegetables, remain hidden within the body during a longer or shorter period until they reach their proper development and produce the disease of which they are the germ. The same thing occurs in yellow fever—its virus requires a certain lapse of time for its development, the infected persons retaining in the mean while the appearance of perfect health. That space of time is commonly, as experienced here, from to five to six days. On some occasions it extends until the fourteenth, and even until the twenty-second, a point which should be taken into account in determining the number of days as a minimum for quarantines and observation, not limiting it without foundation to four, six, or ten days."

In 1814 Dr. Bailly, after carefully sifting the evidence brought forward both by contagionists and non-contagionists, emphatically declares that he has reached the intimate conviction that yellow fever is very often contagious, but that it is not always so.

Unfortunately, however, the above suggestions were not accepted by those who were supposed to be in a better position to judge, and the generality of physicians in the endemic centres of America maintained the opinion that the disease was not contagious in any sense of the word, but was entirely due to mephitic emanations diffused through the air and arising from the soil, from the corrupt waters of the seashore, from decomposed animal or vegetable matter, etc., under the influence of undefined climatic conditions.

In the midst of the prevailing confusion of ideas a disastrous epidemic broke out in 1853, extending far and wide in South and Central America, in the West Indies and in the United States, which aroused a feeling of necessity for immediate action among the members of the medical profession throughout America, but principally in the Southern States of the Union. The report of the sanitary commission of New Orleans on that epidemic displayed the most praiseworthy diligence in collecting numerous and valuable testimony from the various places where the disease had prevailed, and thereby contributed a most important source of information for every student of yellow-fever etiology. Among many other points of interest I shall merely call attention to the following as having a direct bearing upon the subject under consideration:

1. Dr. E. Barton showed, upon reliable data, that in New Orleans a temperature of 60° F. was incompatible with the persistence of the disease in an epidemic form; and in his report (page 283) informs us that at Rio the fever appears when the thermometer is at 77° F., adding that he conceives that too high temperatures, above 90° F., are rather unfavorable.

2. Dr. Pennell, of Rio de Janeiro, pointed out the remarkable fact that during the epidemic of 1853 many people carried the disease from Rio to Petropolis (thirty miles distant, and with an altitude of three thousand feet), and eleven died there, but did not communicate it to a single resident. Many also took it with them to Tijuca (forty miles from Rio and eight hundred feet above the sea level), but in no instance communicated it to the residents at that place.

3. Drs. Axson and McNeil in their report call attention to the remarkable fact that "at Memphis, in the City Hospital, sixty-five cases of fever, carried from this place sick, or taken sick on the river, were treated, and in not one of these instances was there any communication of the disease to either the medical attendants, the nurses, or the other inmates of the hospital. The results were limited to the original subjects, whether these were in recovery or death."

4. Several of the "testimonies" mention the unusual abundance of mosquitos during the prevalence of the epidemic. Judge Louis Selby, in particular, asserts that they were multiplied a hundredfold, and that whereas commonly at Lake Providence, La., they are a dirty yellow, "these had gray rings around their bodies, bit quicker and stung harder than heretofore." With regard to this point Laroche, in the encyclopædic work which he published the following year, calls attention to the superabundance of those insects in

[1] Read before the Pan-American Medical Congress, Havana, February 6, 1901.

Philadelphia during the epidemic of 1797, as recorded at that time, and also in the Southern States in 1853, "when a similar effect was observed."

The report of the New Orleans sanitary commission reproduces the general conclusions of the general board of health of England, in which some of Colomar's remarks about the epidemic of Murcia appear confirmed. But neither in England nor in the United States was any notice taken of the Spanish author's assimilation of yellow fever to a germ disease; on the contrary, every circumstance continued to be so interpreted as to corroborate the idea that the disease was always of local origin and never contagious.[1]

The next quarter of a century following the publication of the above report and of Laroche's classical work constitutes a memorable epoch in the annals of yellow fever. The recognition of albuminuria as a most prominent symptom of the disease, through Blair's admirable work in British Guiana, the remarkable report of Alvarenga on the epidemic of Lisbon in 1857, that of Melier on the epidemic of Saint Nazaire in 1861, Faget's monograph on the relations between the pulse rate and the temperatures in yellow fever, the regular use of the clinical thermometer which gradually became established, the writings of many keen observers (Dutouleau, Cornillac, Bérenger-Féraud, Bemiss, Stillé, Gama-Lobo, Pons y Codinach, etc.), by degrees prepared the way for a clearer understanding of the nature and mode of propagation of the disease.

In 1880 two most important reports were published —one by the yellow-fever commission which was sent to Havana by the United States national board of health to investigate the causes of the so-called endemicity of yellow fever in Cuba; the other by the United States navy department, "on the yellow fever on the United States steamship *Plymouth*." In the former the idea that yellow fever must be a germ disease is clearly expressed; and the fact that it is not of local origin nor originates in the bay is fully demonstrated. Dr. Burgess' experience is given in evidence of the fact that vessels with non-immune crews may lie in the harbor during the height of the epidemic without becoming infected, provided that no intercourse be established with the shore nor with infected ships; and in the "general conclusions" of that remarkable report it is averred that winds fail to infect vessels even at a short distance from the shore, and that other facts also demonstrate that the poison is distributed by winds to only very limited distances. Another important point demonstrated by the commission was that "natives of Cuba as of all other countries, of every age, sex and race (?), are liable to yellow fever; and only those who have had the disease, or have constantly resided in infected localities, enjoy immunity." The facts thus brought to light, together with others previously ascertained, left no alternative but to admit that, although the yellow-fever infection must always be derived from a previous case of the disease, yet the mere presence of susceptible persons and apparently favorable climatic conditions (as in the Memphis hospital in 1853) were often inadequate to reproduce the disease, so that a third factor must be discovered to account for this circumstance. The first attempt at a solution of this problem, I believe, appears in a foot-note in the report on the *Plymouth*, where Dr. Bemiss' opinion is quoted to the effect that the poison of yellow fever "is reproduced chiefly, if not wholly, within the body of the patient, but undergoes some change after its escape from the body, which increases its toxic qualities." This ingenious suggestion, however, afforded no clew as to the circumstances which might or might not enable the passive human germ to undergo the change into an active and virulent one, capable of reproducing the disease. Even supposing that certain unsanitary conditions might provide the necessary "nidus" for the extra-corporeal transformation, the theory afforded no explanation as to the mode of penetration of the virulent germ into the body of non-immunes. Food and drink, as well as contact upon the skin, having been excluded as a means of contamination, only the air passages were thought of as a plausible mode of entrance for the qualified germ; that alternative, however, appeared to me unsatisfactory, inasmuch as it implied diffusibility of the germs through the air, in contradiction with the averred fact that winds influenced very little, if at all, the propagation of the epidemic.

It was upon the above line of reasoning that I conceived the idea that the yellow-fever germ must be conveyed from the patient to the non-immunes by inoculation, a process which could be performed in nature only through the agency of some stinging insect whose biological conditions must be identical with those which were known to favor the transmissibility of the disease. At that time I considered unnecessary the supposition that the human germ required to go through any extra-corporeal transformations in order to become virulent, but in recent years I have also included this consideration in my mosquito theory. My first public allusion to my theory was at the International Sanitary Conference of Washington (session of February 18, 1881), where I expressed the opinion that "three conditions are necessary in order that the propagation of yellow fever shall take place: (1) The presence of a previous case of yellow fever; (2) the presence of a person apt to contract the disease; and (3) the presence of an agent entirely independent for its existence of the diseased and of the sick, but which is necessary in order that the disease may be conveyed from the yellow-fever patient to a healthy individual." In making that statement I had in my mind the Culex mosquito, which I had been for some time investigating from that point of view in Havana, but I had refrained from naming it, not wishing to do so until I had carried out a crucial experiment which I had in project, namely, the application of a non-contaminated mosquito to a severe case of yellow fever, and two or three days later allowing the same insect to sting a non-immune. This I did after my return to Havana. With the acquiescence of Captain-General Blanco twenty recently arrived recruits from Spain were set apart at the Cabañas barracks, and would not be allowed to come to the city except on certain days, when five or six would be brought to my office to have their blood corpuscles counted, and, *passim*, I would try my experiment upon some of them. This I did with the valuable assistance of my friend and constant collaborator, Dr. Claudio Delgado, which I gladly take this opportunity of acknowledging, the more so that I doubt if without his active support I would have persevered during so many years in the defence of a theory which was received only with doubts and sneers. My first inoculation was performed upon a soldier of the third batch that was brought to my office. I ap-

[1] How unprepared even the cleverest men were at that time to reach the true explanation of so many apparently contradictory facts may be judged by the following quotation from Dr. Ed. Barton's elaborate report: "If yellow fever is contagious, *it is a law of the disease*, this it must carry into all places, and under all circumstances (like the smallpox). A *contingent contagion* is a medical misnomer, void of a precedent, and has no parallel in the annals of science. Every device has been resorted to, in the way of experiment, to show the contagious quality of yellow fever, if it existed, but all have signally failed. That it may be *infectious*, under certain circumstances, is admitting nothing more than that it is caused by *impure air*, and that this air can be carried in the hold of a vessel, or any similar mode, by which the air of one place is conveyed to another, or even through clothing (in some special cases and to a very limited extent) is not denied." (Report San. Com. N. O., p. 273.)

plied to the back of his elbow (on the 30th of June, 1881) a mosquito which had stung, two days before, a severe (hæmogastric) case of yellow fever in the fifth day of the attack. On the 9th of July he began to feel unwell, but was sick enough to report himself only on the 14th. He was sent the same day to the Military Hospital, where his case was carefully followed by Dr. Felix Estrada, by Dr. Delgado, and by myself. He presented the typical symptoms of the invasion; his fever reached the maximum of its first paroxysm with 38.8° C. (102° F.) on the second day, the remission fell to 37.6° C. (100° F.) on the third day A.M.; the maximum of the second paroxysm was 38.8° C. (102° F.) the third day P.M.; and defervescence took place on the sixth day. The patient had albumin in the urine from the third day until defervescence, distinct yellowness of the eyes till convalescence, and his gums bled on the fourth day. Four years later I ascertained that he had never had another attack of yellow fever. On the 16th of July I applied a non-contaminated mosquito to a severe case of yellow fever; on the 20th I applied the same insect to my own hand; and, finally, on the 22d, I applied it to another of my twenty soldiers. Five days later, on the 27th, the inoculated soldier was admitted to the Military Hospital with the usual symptoms of the disease, and his case was officially recorded as "abortive yellow fever." He was seen by Dr. Delgado and myself only on the fifth day of his attack (July 31st); he had then scarcely any fever and no albumin. My next experiment was of a different kind, and therefore was omitted from my first paper. I applied a nocturnal mosquito and allowed it to fill itself from a case of yellow fever. After pricking the side of the insect's abdomen I mixed the blood which escaped with a drop of sterilized syrup and fed with it a fresh Culex mosquito, and finally applied the latter to a third soldier (on the 29th of July). Two days later, July 31st, the soldier went to the hospital with a fever which was also recorded as "abortive yellow fever." My fourth inoculation was on the 31st of July; I applied to another soldier a mosquito which had stung, two days before, a fatal case of yellow fever on the third day of the attack. Five days later, on the 5th of August, the soldier returned to have his blood examined, not considering himself sick. His face was flushed, and taking his temperature I found it at 39.6° C. (103.3° F.), and his pulse at 110. He was sent at once to the hospital. He had but one paroxysm of fever (it may have been the second); there was no remission; no albumin was found in the urine and defervescence occurred on the fourth day. His case was recorded at the hospital as "abortive yellow fever."

In the course of the following month I inoculated two other soldiers; one, with doubtful result, having presented himself at my office fifteen days after his inoculation with rapid pulse and fever, but he never took to bed, and no further record of his case could be obtained; a second inoculation on the same man remained without effect. The other soldier never returned to my office, but I ascertained that he had not reported himself sick.

During the two months that my experiments lasted none of the other soldiers of the twenty, except the inoculated ones, experienced any form of yellow fever; and four years later I ascertained that none of the inoculated had been subsequently reported as having had any other attack of yellow fever beyond the one which had followed my inoculation.

Both Dr. Delgado and myself agreed that no further proof was needed to prove the transmission of yellow fever by the Culex mosquito; and on the 14th of August, 1881, I read at a meeting of the Havana Academy of Sciences my first paper on "The Mosquito Hypothetically Considered as the Transmitter of Yellow Fever." The following year I devoted to the study of mild cases of natural yellow fever so as to be able to compare them with the mild experimental ones which might be expected to occur after the preventive inoculations that I intended to undertake as soon as I should find suitable subjects for the experiment; that is, presumably free from previous infection, and about whose medical history I might get reliable information during their subsequent residence on the island. Tables showing the particulars about my inoculations in the one hundred and four persons who have submitted to them in the course of nineteen years (1881–1900) have been prepared. In those preventive inoculations, be it remembered, my principal object was rather to avoid than to seek the development of a severe attack; in point of fact, only seventeen showed any appreciable pathogenic effects after their inoculation. I felt sure, however, that severe or fatal result might follow an inoculation either with several mosquitos contaminated from severe cases of the disease, or from a single insect applied several days or weeks after its contamination, having come to this last conclusion in view of the facts connected with the *Anne-Marie* and the epidemic of Saint Nazaire. The incubation period, in the seventeen who did show pathogenic effects, varied from two to twenty-five days; it was five days in four of them, fourteen days in two, sixteen days in two, and two, seven, nine, ten, fifteen, seventeen, twenty-two, twenty-three, twenty-five, respectively, in the others. Notwithstanding that my technique must now be considered very imperfect, some immunizing effect must have attended my inoculations, for out of the one hundred and four only four (3.8 per cent.) subsequently contracted a fatal attack of yellow fever—two of them the same year, but the other two after five and six years' residence in Havana, and out of the eighty-seven who did not have any perceptible pathogenic reaction at the time of the inoculation, thirty-nine (forty-three per cent.) never had any subsequent attack of yellow fever of any kind during the years of their residence in Cuba.

I must, however, bring to a close this account of the evolutive phase of my mosquito theory and leave to others the satisfaction of describing how, in their more accomplished hands, its perfect "image" has been developed. They will tell how, with almost mathematical precision, they have proved, not only that the Culex fasciatus does transmit the disease from one patient to the next, but also that when the contaminated mosquito has been excluded, the yellow-fever infection becomes intransmissible. Not, I do believe, since the days of Jenner, one hundred years ago, when that great benefactor of mankind, after years of fruitless efforts, succeeded in convincing the medical profession all over the world of the incontrovertible reality of the cowpox vaccination, has another achievement been recorded equal to that of Drs. Reed, Carroll, and Agramonte.

Echinococcus Cysts of the Kidney.—Professor Rummo reports a case in which a tumor reached from nearly the left iliac crest inferiorly to the vertebral column posteriorly and to the sixth rib above. Its margins were rounded, its consistence was hard and elastic. It was somewhat mobile. The author gives at length the differential diagnosis between tumors of the kidney and spleen and retroperitoneal tumors, and the reasons for concluding that this was a case of renal tumor. The introduction of a needle and the withdrawal of a clear fluid containing echinococci settled the diagnosis. Before resorting to operation, the author intended to experiment with Baccelli's method of injecting bichloride of mercury into the sac.—*La Riforma Medica*, December 4, 1900.

INVESTIGATIONS UPON CORPOREAL SPECIFIC GRAVITY, AND UPON THE VALUE OF THIS FACTOR IN PHYSICAL DIAGNOSIS.[1]

By HEINRICH STERN, Ph.D., M.D.,
NEW YORK.

Absolute Body Weight.—The determination of the absolute weight of an individual has for years been regarded as an important adjuvant in the practice of the physician and the medical examiner in general. Frequently, however, the absolute body weight does not reflect the real physical condition of the organism. It is true, both the marasmatic and the corpulent present abnormal absolute body weights, but exceedingly light or heavy people need not necessarily be afflicted with a wasting disease or with obesity.

The phenomenon of rise and fall in the absolute body weight, *per se*, is but of limited diagnostic significance. In itself, the patient's absolute weight does not disclose definitely a morbid systemic state, as is evinced, for instance, by the one symptom of chronic glycosuria. To the therapist, on the other hand, the absolute body weight is of a somewhat greater value: its decrease or increase points out to him whether his treatment is taking effect or not; that is, whether the emaciated has gained or the stout has lost in absolute body weight.

Most fraternal beneficiary organizations and life insurance societies require their examiners to ascertain the body weight of an applicant; yet in every instance it is the absolute weight which is determined, though the life assurance companies, as a general rule, seek to consider the relation of body height to body weight. The majority of these institutions—in the United States—have a fixed and common standard requiring for each centimetre of body height 446.45 gm. of body weight, which is equivalent to two and one-half pounds for every inch, but concede fifteen per cent. underweight and twenty per cent. overweight to the applicant otherwise regarded as good risk. Thus, although the employment of a fixed standard is certainly an improvement over the primitive method of ascertaining the absolute weight *per se*, many totally sound people are prevented from obtaining insurance and the companies deprived of additional business.

The specific weight of an individual and the density of his structures have been assigned entirely too insignificant a rôle in medical diagnosis and therapy. Jaeger's voice, raised more than twenty years ago in behalf of the consideration of the specific gravity of the body for clinical purposes, has passed away unheeded;[2] for it is the density of the organism and its tissues, and not its absolute weight, which discloses with an almost absolute degree of certainty its soundness as well as a variety of systemic disturbances and alterations.

Methods for the Determination of the Corporeal Specific Gravity.—By corporeal specific gravity is understood the proportion of absolute body weight to the weight of the volume of water or air displaced. Troublesome procedures and lack of ready facilities seem to be the main reasons why the specific gravity of the body has not become a more potent factor in medical diagnosis.

Apparatus for practical use in the determination of corporeal specific gravity have not been devised as yet. Jaeger[3] who estimated the body volume by a series of measurements, which, according to his own statement, gave results sufficiently accurate for purposes of comparison in a number of persons, but not exact enough for the determination of one individual's density *per se*, is of the opinion that this could be best accomplished with the assistance of a modified Kopp volumeter. Kopp's volumeter is based upon the following principle:

If a mercury manometer is properly attached to a closed chamber containing air and the latter by means of a tightly fitting piston is compressed to a known volume, the rise of the mercurial column may serve as an indicator of the quantity of compressible air contained in the chamber. The smaller the amount, the higher rises the mercury, provided there is an equal and absolute diminution of space. If a solid body is brought into this chamber the air contained in it becomes still more condensed, which results in the rise of the mercurial column. The volume of the solid body may be exactly determined by a comparison of the manometer readings obtained prior and during the former's presence in the chamber.

An apparatus based on this principle, but greatly modified for the special purpose, may be used with advantage in the determination of the corporeal volume. The results obtained with the assistance of such a volumeter—theoretically speaking—should be more accurate than those arrived at by the employment of any other conceivable apparatus. As a matter of fact, this device for volume mensuration of the living organism offers but one objection, viz., the individual, by his entrance into the chamber, changes the condition of the air contained in it by imparting to it a somewhat higher temperature and by communicating water vapor. Instruments of precision, such as thermometer and hygrometer, are therefore indispensable for more exact determinations.

In my own experiments I have ascertained the corporeal specific gravity by employing the Archimedean principle. The density is thus obtained by dividing the amount of the absolute weight of the body by the loss of weight which it sustains when suspended in water. For instance, if the absolute weight of an individual is 65 kgm. and his loss of weight in the water amounts to 61 kgm. his specific gravity will be $\frac{65}{61} = 1.066$; therefore, the volume weight of the individual's body is greater by 0.066 or by $\frac{1}{15}$ than that of water.

I have discarded the huge hydrostatic balance of my own construction which I employed in my early experiments, as I found that simple submersion in water, without suspension, gives almost identical results. From the volume of the water displaced the corporeal volume weight is easily ascertained. An individual whose absolute weight, for instance, amounted to 64 kgm. displaced 59.75 kgm. of water by actual weight; his volume weight, therefore, was $\frac{64}{59.75} = 1.067$.

The determination of the corporeal density by the Archimedean method also offers one drawback, which, for practical purposes, however, especially if certain precautions are taken, I deem even of less importance than the inaccuracy eventually arising when a Kopp volumeter is utilized. I refer to the air contained in the lungs and intestinal tract which produces a slight increase in the body volume and consequently a greater displacement of water. This fact derogates, it is true, from the absolute value of the method, but it is certainly of little practical moment, as the inflation due to the normal amount of air within the organism does not cause a material change in its litre weight. Moreover, the body air, being a constant though somewhat varying constituent, may be included in all determinations. Besides this, the intestinal gases may be reduced to a minimum if the individual's bowels have been evacuated prior to ascertaining his body density, and by submerging him during the period of forced expiration the thorax will not be overvoluminous.

The determination of the corporeal litre weight by

[1] Read at the meeting of the New York State Medical Association, October 18, 1900.

[2] "Seuchenfestigkeit und Constitutionskraft und ihre Beziehung zum spezifischen Gewicht des Lebenden," Leipzig, 1878.

[3] *Loc. cit.*, p. 132.

the submersion method gives far more accurate results than can possibly be obtained by a series of body measurements. On the other hand, volumetric determinations by means of a modified Kopp apparatus seem preferable to the rather crude Archimedean method; however, the mechanics I consulted about the construction of a Kopp apparatus thought it impracticable and would not guarantee its accurate working. Moreover, the employment of such an apparatus would call for tedious mathematical calculations.

The Volume Weight of the Living Organism.—The density of the animal body discloses in a most interesting manner the physical condition of its structures. Among the principal tissue constituents there is but one body of a lesser density than water. Fat derived from the human organism has an average specific gravity of 0.932. Mitchell[1] found even a lesser degree of density—0.9033 at 25° C. and a consistency somewhat below that of butter fat. Fat is normally found throughout the human organism, partly as the principal element of adipose tissue, nearly eighty-five per cent. of which is composed of fat, and partly uncombined, as in the chyle, lymph, blood, serous fluids, milk, and other secretions. It frequently appears pathologically—occurring as fatty infiltration or as fatty degeneration, altering by its presence in excess the density of the affected tissues and organs and of the body in general. Abnormal fatty deposits reduce the specific gravity of the individual in the ratio of their preponderance over other corporeal components, principally bone and muscle tissues. On the average 1.4 per cent. of fatty matter is present in bone tissues, whereas in the healthy muscle it occurs to the extent of about three per cent. In the male the bony and muscular structures possess a higher specific gravity than in the female. The muscles of the latter are of a lighter color, and their fibres are softer and more subtile. While contractile tissue forms almost the entire muscle in the healthy male, a relatively large quantity of cellular and adipose tissue is deposited in the muscles of the female, bolstering up the interspaces and thus imparting to the feminine body its characteristic rounded and undulated appearance. Large accumulations of fatty material are met with especially in the glutei muscles of the female, where it is often deposited in exceedingly thick layers of great consistence. The volume weight of the component parts of the female organism being, as a general rule, lower than that of similar parts in the male, naturally gives occasion to a lesser specific gravity of the female body *in toto*. While there exists a discrepancy in the specific gravities of the healthy male and female, the density of both is physiological. If, however, a masculine subject possesses the volume weight of a normal woman, he in all probability has a diminished vital resistance or is pathologically affected, and *vice versa*, the female showing a corporeal specific gravity as high as that of a normal man, in all likelihood has no or but a scanty catamenial flow, or may be afflicted with an atrophic or another metabolic disorder.

In childhood the corporeal specific gravity is below the density of the adult organism, and the mean specific gravities of both sexes in very young children are not at variance.

Water forms almost seventy-five per cent. of the total absolute weight of the adult, and in the neighborhood of ninety per cent. of that of the embryo. The quantity varies in each group of tissue. The mean proportion of water in some of the textures of the adult is as follows:

	Per cent. in weight		Per cent. in weight.
Enamel	0.2	Nerves	78
Teeth	10.	Glands	79
Bones	13–15.	Blood	78–80
Cartilage	57–70.	Cellular tissue	80
Muscles	72–76.	Kidneys	82
Brain	75–78.		

[1] Chem. Centralblatt, 1896, ii., 498.

The various tissues, it will thus be seen, vary greatly in their consistence.

The fluids of the body naturally are composed of water to a far greater extent than are the tissues. The following body fluids contain of water:

	Per cent. in weight.		Per cent. in weight.
Milk	83–92	Urine	90–99.
Bile	87–00	Gastric juice	98–99.
Spermatic fluid	90–95	Liquor amnii	98–99.
Chyle	90–95	Saliva	99–99.75
Lymph	93–96	Sweat	99–99.75
Pancreatic juice	95–97		

In old age the amount of water contained in the different tissues is considerably smaller and the fluids of the body are greatly diminished in quantity. Senility, which is virtually nothing else but physiological atrophy, is characterized by a general shrinking and drying up of the body textures; hence, the volume weight of the aged is above that of individuals in middle life.

The quantity of water in the living organism is dependent upon two main factors, viz., the cellular absorptivity and the hydrolytic force of the system in general. In the state of physiological retrogression the potency of these factors is more or less diminished. The fluctuations in the density of the body are for the most part due to its greater or lesser contents of water. The more of this is held in the fluids of the body, and especially the more the tissues are saturated with it, the smaller will be the volume weight of the organism.

The inorganic substances of the body, constituting three to six per cent. of the total body weight during adult life, play an important rôle in the corporeal density. Calcium phosphate, the most abundant of all mineral salts entering into the composition of the animal textures, forms almost sixty per cent. of all osseous tissues. If the proportion of the latter to the total body material is 1 : 15.5 and if the absolute weight of the total body substance amounts, for instance, to 75 kgm., the weight of the bony tissues would be 4,830 gm., and that of the calcium phosphate 2,898 gm.

The amount in which this salt occurs in the bones is almost six times greater than the combined quantity of all other inorganic constituents of the bony texture. Its office in the organism seems to be rather a mechanico-physical one than one of a chemical nature. This is evidenced by the inconsiderable quantities in which it is found in the body fluids by its limited metabolization and by its peculiar deposition in the firmer structures. The rigidity and density of the osseous and cartilaginous tissues are practically dependent upon their contents of phosphate of lime. The volume weight of a bone is the greater the more the calcareous element preponderates. All other mineral substances of the animal body are practically of no moment in the determination of the corporeal specific gravity. The widely distributed sodium chloride even, the most important of all inorganic body constituents by reason of its potency in the processes of nutrition and other phenomena of life, does not influence the corporeal density, as it exists in the organism in quantities little more than 100 gm. Within certain limits, however, the greater or lesser presence of this salt in the organism may cause fluctuations in the density of the most important animal tissue, the blood.

The blood—in point of density—occupies a place between the fluid and the solid components of the animal body. Stintzing and Gumprecht calculated the

mean normal percentage of water in the blood to be 78.4 for the male and 80.2 for the female. Becquerel and Rodier arrived at similar figures, 77.9 per cent. for the healthy man and 79.1 per cent. for the healthy woman. The same investigators, according to v. Limbeck,[1] recorded fluctuations in the blood density in the healthy male between 1.058 and 1.062, in the mean 1.0602; and in the female between 1.054 and 1.060, in the mean 1.0576. Lloyd Jones found as normal values densities between 1.035 and 1.068; Hammerschlag, between 1.056 and 1.063, and Peiper, between 1.0455 and 1.0665 (v. Limbeck).

My own observations, which extend over a period of almost five years, were made partly by means of the method of Roy, partly by that of Hammerschlag. The blood density of the healthy adult male between the twentieth and fiftieth year of life I found to range between 1.057 and 1.0635, and that of the healthy woman, during the same period of life, between 1.051 and 1.061. In advanced age above the fiftieth year I found, as a general rule, an increase in the specific gravity of the blood. Thus I found a blood density of 1.0695 in a healthy male of seventy-three and one amounting to 1.0685 in a healthy woman of sixty-two.

Lloyd Jones (v. Limbeck), who has made extensive studies as regards the blood density in the different periods of life, informs us that the specific gravity of the blood—in both sexes—is highest (1.066) soon after birth. After the second week of life the density declines to 1.048 in boys and to 1.050 in girls, to remain at this minimum until the close of the second year. Thereafter a slow but steady rise sets in, which culminates in the male between the thirty-fifth and the forty-fifth year and in the female after the menopause. In the advanced period of life the blood density—in both sexes—is raised once more. It thus attains toward the close of life a similar degree of concentration as at the time of birth.

Density of Blood an Indication of Corporeal Density.—The volume weight of an organism in the physiological as well as in the pathological state is reflected in the specific gravity of its blood. A high blood density is an indication of a high body density, and *vice versa*, a non-transitory hydræmic condition is mostly met with in an organism of low specific gravity. Slight deviations in the density degrees of blood and body are almost always the rule; exactly analogous figures are hardly ever obtained. This difference, however, seems to be rather due to inaccuracies of the methods for the determination of the specific gravities of both blood and body than to an unequal distribution of the watery contents of the animal organism.

The volume weight of the living organism and the density of its blood were ascertained by me in the following instances:

1. Normal man, aged thirty-one years. Absolute weight, 80.5 kgm. Volume weight, 1.066. Blood density, 1.0605.

2. Normal man, aged twenty-eight years. Absolute weight, 68 kgm. Volume weight, 1.0675. Blood density, 1.063.

3. Normal male youth, aged seventeen years. Absolute weight, 64 kgm. Volume weight, 1.067. Blood density, 1.0615.

4. Normal man, aged twenty-five years. Absolute weight, 59.5 kgm. Volume weight, 1.0643. Blood density, 1.059.

5. Normal man, aged thirty-three years. Absolute weight, 84.25 kgm. Volume weight, 1.0664. Blood density, 1.0605.

6. Normal man, aged twenty-four years. Absolute weight, 61 kgm. Volume weight, 1.07. Blood density, 1.0635.

7. Normal man, aged twenty years. Absolute weight, 55.5 kgm. Volume weight, 1.069. Blood density, 1.063.

8. Normal man, aged twenty-three years. Absolute weight, 63 kgm. Volume weight, 1.0678. Blood density, 1.0615.

9. Normal man (colored), aged twenty-eight years. Absolute weight, 70.5 kgm. Volume weight, 1.0682. Blood density, 1.062.

10. Normal man, aged twenty-nine years. Absolute weight, 67.5 kgm. Volume weight, 1.067. Blood density, 1.061.

The blood in every one of the heretofore cited instances was obtained by puncturing the tip of the middle finger of the left hand, without exercising any friction previously. The latter precaution was taken to secure the blood at as near its normal temperature as possible, for the reason that the blood density becomes lessened even if but a slight momentary temperature elevation has ensued.

Another precaution which I have taken in all my investigations was never to puncture for blood after the individual, the specific gravity of whose blood was to be ascertained, had perspired. Perspiration invariably calls forth an increase in blood density. For obvious reasons water at its maximum of density—40° C.—could not be utilized. However, by weighing the amount of water displaced, the difficulty was overcome.

These observations tend to demonstrate the relation between corporeal and blood density in the healthy individual. The higher degrees of blood concentration, without exception, corresponded with a higher specific gravity of the total organism. From my observations, it is true, a fixed ratio between the two density degrees cannot be learned; nevertheless, such a ratio may exist, particularly in the healthy body of adults—males and females.

We are certainly not far from the truth if we accept the mean difference in the density degrees of body and blood as recorded in my observations as the deviation standard. The two densities varied from each other on the average 5.8 points. The standard or coefficient for the estimation of the corporeal specific gravity of healthy adult males from the blood density would be + 5.8, or in round figures + 6; for the determination of the blood density from the specific weight of the body the coefficient −5.8, or in round figures −6 will give approximate results. Hence, if an individual's blood density was found to be 1.061, for instance, his approximate volume weight will be 1.067, and *vice versa*, a corporeal specific gravity of 1.067 presumably concurs with a blood density of 1.061, or thereabout.

My observations upon the relation of the volume weight of healthy adult women to the density of their blood are as yet quite limited. However, there is no doubt that the mean deviation in the two densities will not differ greatly from that which I have found in the male.

The connection between blood and body density is found during all the periods of life. One is reflected by the other, in health and in disease.

My experiments as regards the relation of both densities in children and in individuals above the fiftieth year, while not very numerous as yet, have clearly demonstrated the intimate connection of these two factors.

Instead, therefore, of ascertaining the corporeal density *per se* by one of the aforementioned laborious methods, it is far more practical and will give almost analogous values by calculating it with the help of a coefficient from the degree of blood density. When it has been generally conceived that the corporeal volume weight can be computed by such a simple proce-

[1] "Grundriss einer Kleinschr. Pathologie des Blutes," zweite Auflage, January, 1896.

dure, then the moment has arrived when it will be one of the salient features in physical diagnosis.

The Corporeal Specific Gravity as a Factor in Physical Diagnosis.—The information furnished by the body density of an individual will assist to disclose the following points:

First: Body soundness. A volume weight in the healthy adult male below 1.063 or above 1.073 denotes unsoundness of the organism. The lesser density is indicative of a general texture satiation with water or of the preponderance of adiposis, or of both conditions together. The higher degree of density reveals a disturbed metabolism, a general atrophic or sclerotic state, or premature senility.

Second: Body immunity. A volume weight below the minimum degree of normality signifies that the system is predisposed to infectious diseases, and one above the maximum of normality announces its susceptibility to or the presence of eliminative disorders.

Third: Qualifications as to physical work. A body whose tissues are satiated with water or infiltrated with abnormal quantities of fatty material cannot during a certain period perform that amount of work which can be accomplished by another organism of the same age and absolute body weight but of normal specific gravity; the individual with abnormal high volume weight also lacks the strength and endurance of one with a lesser but normal density.

Fourth: Probable duration of life. All given conditions being alike, a person of normal volume weight will attain a greater age than one with an excessively low or high density. Individuals, therefore, whose specific gravity is abnormal, should be considered bad risks by life assurance examiners.

Special pathological processes, in as far as they are the originators of abnormal body densities, may often be recognized by the condition of the latter.

In phthisis pulmonum the blood density may not stand in exactly the same relation to the body density as in the healthy organism, that is, the discrepancy between the degrees of the specific gravities of both may be either above or below that in the normal body; however, it seems to be beyond question that there always exists a direct relation between the density of blood and that of the body. The blood density frequently, but not in all instances, varies during the different stages of the tuberculous affection.

The blood of a great number of phthisical patients which came under my observation at various stages of the disease showed an average density of 1.055. The highest blood density observed by me in a phthisical male individual was 1.058, the lowest 1.0505. The lessened specific gravity of the blood in phthisis pulmonum may well serve as an indication of a diminished corporeal volume weight.

I have found abnormal blood densities—to which in most instances proportionate abnormal body densities undoubtedly corresponded—in a variety of metabolic disorders, in renal maladies, in oligocythæmia and other blood affections, and in many febrile conditions.

It is, however, beyond the scope of this paper to enter more fully into the discussion of the relation of corporeal density to certain pathological states; this I reserve for a future communication.

56 East Seventy-sixth Street.

Enuresis and Irritable Bladder in Children.—The treatment which the author especially recommends is hot sitzbaths once or twice daily, the appropriate treatment of accessory causes, the restriction of fluids in the evening. At night the child is laid so that the head is lower than the hips. In older children local treatment through the endoscopic tube is recommended.—Bierhoff.

THE USE OF THE AQUEOUS EXTRACT OF THE SUPRARENAL CAPSULE AS A HÆMOSTATIC.[1]

By W. H. Bates, M.D.,
New York.

In this paper I wish to emphasize some facts already published, and to call attention to some new uses of the suprarenal substance as a hæmostatic. After using it for six years I still believe it to be the most powerful known astringent and hæmostatic. When properly used it will control hemorrhage from all mucous membranes.

Preparations.—The successful use of the extract depends very much on the preparation employed. For local use a solution, which is efficient when applied to the normal mucous membranes of the eye or nose, should make it white in less than one minute. Satisfactory results have been obtained with the following: One part of the dried and powdered gland is mixed with ten parts of water. This forms an emulsion which has been successfully employed to control or prevent hemorrhage after operations on the nose and urethra. It is important that the mixture be freshly prepared, as it soon spoils; sometimes in two hours. For use in the eye or ear the emulsion should be filtered. The solution may be sterilized by heat without losing its efficiency.

For internal administration to control hemorrhage the dried and powdered gland is efficient; it keeps indefinitely. Tablets are useless. Solutions of the extract prepared from the dried gland and from the alkaloid are also satisfactory in controlling hemorrhage from the internal coats of the eye, hemorrhage from the lungs, stomach, and uterus. One does not need to use the hypodermic method, as all the preparations are absorbed by the mucous membrane of the tongue immediately, and the effect follows in less than one minute.

Eye.—Operations on the eye muscles cannot be made bloodless unless the visible vessels are made to disappear by the action of the extract. When the scleral veins are cut, the bleeding may be considerable and the blood invades the subconjunctival tissue for some distance. To control the bleeding a hypodermic syringe is useful to apply the solution to the cut vessel; but little benefit follows the application of the suprarenal to the outside of the blood clot. In lacrymal operations the nasal duct has been incised without the loss of a drop of blood by using the extract frequently during the operation alternately with cocaine, especial care being taken not to cause pain. As soon as the patient feels pain the suprarenal extract ceases to prevent hemorrhage.

Ear.—Dr. G. M. Black has removed the membrana tympani and ossicles without hemorrhage by the use of suprarenal. Dr. Wendell Phillips has found the extract a valuable hæmostatic in operations on the middle ear with the patient under ether. During operations on the mastoid the spurting of the incised arteries of the soft parts is controlled at once by the local use of the suprarenal solution, and the oozing of blood which fills the wound after chiselling the bone has also been materially lessened.

Nose and Throat.—The local action of the suprarenal is less when the parts are inflamed, swollen, or tender, and when the patient is depressed. Epistaxis even in "bleeders" can usually be controlled at once, in less than one minute, when the solution is applied directly to the bleeding surface. It is necessary in some cases to use a syringe. The internal administration is also valuable in controlling nasal hemorrhage. Operations on the septum can be made bloodless by

[1] Read before the New York Pathological Society, December 12, 1900.

keeping the parts blanched white with suprarenal during the operation. Secondary hemorrhage is lessened. I make it a rule to give the patient some suprarenal solution for use at home in case the after-bleeding becomes annoying. Since I have learned the great value of the extract in controlling nasal hemorrhage after operations, I have not used "tampons."

Before closing this short paper I wish to report some new uses of the suprarenal in which the internal administration controlled hemorrhage.

Dr. F. A. Mandeville treated a girl who for two years had suffered daily from nosebleed. The attacks also occurred occasionally at night. The internal use of the suprarenal, gr. iii. t.i.d., was followed by immediate relief. When the suprarenal was stopped a relapse occurred. Suprarenal was again administered and the hemorrhage ceased.

Dr. E. L. Kellogg treated a case of hæmophilia in a child aged one year. The frænum of the upper lip had been cut. Hemorrhage followed, which continued without intermission three weeks. It was treated with styptics, the actual cautery, and by pressure without benefit. Suprarenal solution applied locally stopped the bleeding at once for a time. It was also administered internally. In thirty-six hours the relief was permanent.

Dr. F. J. Quinlan treated a man with hemorrhage from the stomach with nitrate of silver and other astringents without benefit. Pulverized suprarenal, gr. v. t.i.d., was prescribed and relief followed at once. The patient also suffered from bleeding hemorrhoids, which were greatly relieved by the suprarenal.

Dr. J. J. Miller, in consultation with Dr. H. C. Dalton, observed the suprarenal stop hemorrhage in a second case. It was administered (gr. v.) every three hours.

Dr. J. B. Moore treated two cases of epistaxis associated with organic heart disease by gr. xx. of the powdered gland administered by the stomach. The remedy was also applied locally. The bleeding ceased at once. In one case of hæmoptysis the internal administration of the powdered gland, gr. x. every half-hour for six doses, stopped the bleeding. The patient had phthisis pulmonalis and died five days later of exhaustion.

In one case of post-partum hemorrhage the uterus was packed with a large tampon of cotton soaked in a saturated solution of the extract. Ten grains of the powdered gland were also administered internally and a second dose was given half an hour later when the tampon was removed. The hemorrhage had ceased and the patient made a rapid recovery. He is the first to report the local use of the suprarenal extract in post-partum hemorrhage.

Dr. F. A. Mandeville, of Rochester, N. Y., reports the following, which is the first case in which the internal administration was used to prevent nasal hemorrhage during an operation, and in which it was employed after the operation to prevent secondary hemorrhage. A woman, aged thirty-seven years, had a myxomatous growth in the left naris. It bled readily when touched with a probe. An operation for its removal was followed by severe and alarming hemorrhage. Two months later the growth returned. The suprarenal, gr. iii. chewed, was administered every three hours for two days before and on the day of the second operation. Under chloroform the growth was removed in the same manner as at the first operation, with the loss of an insignificant amount of blood. It was noted that the slight hemorrhage ceased almost immediately after the completion of the operation. No dressing was applied. The patient recovered from the chloroform within an hour. The suprarenal was administered every hour, gr. iii. chewed for a day, then every two hours for another day. No secondary hemorrhage followed. The doctor has used the suprarenal internally in other cases with success in lessening primary and preventing secondary hemorrhage after nasal operations.

Urethra.—The successful use of the extract as a hæmostatic after internal urethrotomy has been published by Dr. J. A. Moore and after external urethrotomy by Dr. E. L. Kellogg.

Uterus.—Dr. G. T. Harrison reported the use of suprarenal internally to control uterine hemorrhage from subinvolution. One case of hemorrhage from cancer relieved at once by the extract is on record. A second case was successfully treated by Dr. F. Churchill.

The following case of uterine hemorrhage is reported by Dr. S. Floersheim, and is the third on record in which the internal administration of suprarenal controlled hemorrhage from cancer of the uterus: Mrs. S——, aged forty-three years, was operated upon in August, 1900, for uterine cancer by Dr. West at the New York Post-Graduate Hospital. Not all of the diseased tissue could be removed. The patient afterward suffered considerable pain, for which morphine was administered frequently. On December 4th she had a copious hemorrhage but refused treatment, as she wished to die. This continued for two days and the patient became very weak. Two three-grain capsules of the suprarenal powder were given the patient to chew and swallow without water. She was first told that the medicine was intended to relieve the pain. Within two minutes the hemorrhage, to the surprise of the attendants, was completely controlled. Sixteen days later no hemorrhage whatever had occurred.

The first case of hæmaturia successfully treated with the suprarenal gland is reported by Dr. S. Floersheim. A woman, aged sixty-four years, had suffered two years with vesical tenesmus and a feeling of burning or heat over the hypogastrium. She became very weak and had been confined to her bed two weeks. Treatment with nitroglycerin, digitalis, ergot, spiritus ætheris nitrosi, hyoscyamus, belladonna, salol, infusion of buchu, and potassii acetas during her illness was followed by no benefit. Finally all treatment was stopped and suprarenal powder, gr. iii., was chewed and swallowed without water. The dose was repeated three hours later. To the astonishment of her physician and friends the patient stated that after the first dose she was immediately and completely relieved of all her symptoms. Two hours later she was attending to her household duties and felt perfectly well. The hæmaturia or other symptoms had not returned two months later. The patient was cured by only two doses of suprarenal.

Conclusions.—1. The suprarenal extract is the most powerful known hæmostatic, and has, when properly used, no objectionable properties.

2. When it is used locally, hemorrhage from mucous membranes can always be controlled.

3. The internal use of the extract as a hæmostatic is efficient in some cases.

4. The suprarenal extract, when it controls hemorrhage locally or by the internal administration, does so in less than one minute.

50 East Sixty-fourth Street.

Retinitis Albuminurica in Pregnancy.—Retinitis occurring in pregnancy gives evidence of a toxic condition of the blood which endangers the life of both mother and child, and unless remedies prove efficacious, abortion is justifiable, especially when it occurs in the early stages of pregnancy, or if a previous pregnancy has already injured the retina or the optic nerve.—Francis W. Alter.

THE CLINICAL SIGNIFICANCE OF DULNESS IN APPENDICITIS.

By H. T. MILLER, M.D.,

SURGEON, CITY HOSPITAL, SPRINGFIELD, OHIO.

In reviewing the literature on appendicitis for the past year one is strongly impressed with the difference of opinion as to the proper course to pursue in the treatment of this disease. There have arisen two factions to this interesting question. On the one side you see arrayed statistics seemingly as formidable as those on the other; one proclaiming to the world that he can as successfully treat this disease by remedial measures as the surgeon can by operative intervention; and in some instances you even read of those who discountenance the resorting to the knife, and positively proclaim that appendicitis is and can be successfully treated by other measures than operative. That they have grounds to formulate such an opinion is at once made apparent by the heated discussions that have taken place in nearly all the society meetings within the past year. You even find not a few of the most prominent surgeons denouncing surgical interference in some cases as unnecessary, holding that there are cases that can be and are successfully treated by other means than operative.

Logically, one cannot but deduce from this difference of opinion that our knowledge of this disease is not such as to lead us to any definite conclusions as to the proper course to pursue, for when one positively states that he has had cases of appendicitis that he has successfully treated without resorting to the knife, one must give ear and feel that a mistake in diagnosis could not have been made in every instance. This being the case, the surgeon is forced to take a more moderate course and not view the opinion of the physician as reprehensible ignorance. Until within a very few months a physician would have hesitated to announce that he had had a case of appendicitis, and had successfully treated it with other means than surgical. For fear of his diagnosis being questioned he would maintain a discreet silence. Heretofore he has remained among the silent majority, allowing the audible minority the whole field.

That a reaction is taking place no one who keeps himself well informed can for a moment question; and that this reaction is for the good we all must admit. Not that I would place this disease in any other category than that of surgery, but rather that I would, from what knowledge I have had from clinical experience and from the perusal of current literature, say that the disease can be treated conservatively up to a certain point; and when that point is reached all conservative measures should be abandoned and radical measures at once taken. I can say with considerable confidence that all, with but few exceptions, have agreed that when the stage of the formation of pus has arrived operative intervention is inevitable. In arriving at a diagnosis of appendicitis, considerable weight should be attached to the presence of an actual inflammatory exudate in the appendical region. If this cannot be detected, and there is simply local tenderness in the iliac region, with some fever, Dr. Bull has said he is rather disposed to wait.[1]

In a certain percentage of cases of operation for appendicitis the appendix is found in a healthy condition. It is a well-known fact that appendicitis has been mistaken for pneumonia and tonsillitis. There are certain conditions of the peritoneum, cæcum, and even the appendix that are not operable. Sentiment should play a very minor part in an age in which we are so very practical; yet one cannot but feel that a serious check is placed upon the art of surgery when an eminent surgeon operates upon a case of appendicitis, with only the symptom of pain to suggest appendicitis, and finds a normal appendix, and the patient dies within forty-eight hours after the operation. One distinguished surgeon has asserted that even should we operate and a mistake be made, the mistake is generally in favor of operative intervention. I think I can say with considerable confidence that should the profession freely express its opinion on this point, it would never agree with this eminent surgeon. We cannot dispute the fact that more cases of "inflammation of the bowels" are saved to-day than there were a decade ago. We can well afford to be more circumspect in our management of these diseases of the bowels. A sentimental view of appendicitis is taking the disease in the abstract, 'tis true, but nevertheless it should hold good in all cases, for we are dealing with life, and that should always be of paramount importance.

The symptoms of this disease, from the moment of its invasion, through its gradations up to the formation of dulness, have been ably described in classical papers, so I will leave these to the knowledge of the reader, and give my reasons why I should be disposed to wait for the formation of dulness in the appendical region before attempting operative intervention. If the alarming symptoms of an acute attack subside within twenty-four to forty-eight hours, we certainly can afford to wait; if, however, there should be no indication of a subsidence in the severity of the symptoms within that time, and we can detect the presence of an actual inflammatory exudate, we would be unwarrantably jeopardizing the life of the patient by deferring operative intervention. We have been taught that pus as pus is never absorbed, then its presence is a veritable sword of Damocles, and the sooner it is removed the better it is for the patient.

In my opinion sufficient stress has not been placed upon the "point of dulness." In every instance in my experience in which I have relied upon this symptom I have been led to a correct conclusion. In cases without any pronounced inflammatory symptoms and in which the dulness was marked, I found the appendix indurated and adherent to the adjacent tissue.

Case I.—A boy, aged nine years, returned from school suffering with severe pain in the region of the appendix. Temperature, 101°; pulse, 100. On the second day the symptoms were about the same, excepting that the pain had increased. On the third day the temperature and pulse increased, with marked dulness over the region of the appendix. I strongly advised operation. This being refused, I retired from the case. A colleague, called in, continued with the oil-and-salts treatment. Two weeks later I was called in to operate, which I refused, as the patient was moribund—dying the following morning. Post-mortem was requested but not allowed.

Case II.—N——, aged forty-six years, was admitted to the hospital March, 1898, in the fourth attack of appendicitis. Temperature, 99°; pulse, 100. Pain in the appendical region was marked, but there was no dulness. Operation revealed the appendix in a healthy condition, but firmly adherent to the abdominal wall. The appendix was removed and the pain relieved. Recovery.

Case III.—A young lady had pain in the appendical region, which was increased on deep pressure; temperature, 100°; pulse, 110. She was ordered gr. $\frac{1}{10}$ of calomel every hour, with oil-and-salts treatment and rectal injections. The patient improved rapidly, and was discharged cured. It is now over a year and a half ago, and there has been no return of any of the symptoms.

Case IV.—M——, aged nineteen years, suffered severe pain in the region of the appendix, with fever and increasing pulse. Dulness was pronounced.

[1] Medical Record, May 26, 1900.

Operation was not allowed. Calomel, oil-and-salts treatment, and rectal injections were ordered. Death occurred four days after he entered the hospital. Post-mortem examination revealed a gangrenous appendix in a large abscess and suppurative peritonitis.

Case V.—G. P—— entered the hospital in June, 1898, suffering severe pain in the region of the appendix, with marked dulness, fever, very rapid pulse, free sweating, and vomiting. Operation was performed on the afternoon of the day of admission. A gangrenous appendix and omentum and a large abscess were found. The appendix and about six inches of the omentum were removed. Recovery with hernia ensued.

Case VI.—S——, aged nine years, was admitted to the hospital suffering from an acute attack of appendicitis. Dulness was pronounced. Operation was performed four hours after admission. About four ounces of pus were found. The appendix was not removed on account of intense adhesions. Recovery.

Case VII.—S—— was admitted in December, 1898, to the hospital, after having driven five miles, suffering from an acute attack of appendicitis. Dulness was marked. Operation was performed the following day. Pus was found, and the appendix removed. The patient did well until the eighth day, when he died of suppurative peritonitis. I cannot help feeling that the mistake made in this case was the use of hydrogen peroxide in cleaning out the abscess cavity.

Case VIII.—G. P——, second attack, March, 1898, with fever and increased pulse. No dulness was present. The attack lasted four days under regulation treatment. Recovery.

Case IX.—W——, aged twenty-one years, in the last stage of an acute attack of a week's duration. The fever was high and the pulse thready. Operation was performed soon after admission to hospital. A large quantity of pus and a gangrenous appendix and intestine were found. The abdomen was washed out with decinormal salt solution and the wound closed. Death ensued the following day.

Case X.—Miss W—— had a third attack July, 1898. Fever and pain had been present for four days. There was no dulness. Apparently she recovered, as there has been no return of either fever or even the slightest sensitive spot.

Case XI.—T——, aged twenty-two years. The abdomen was tympanitic, with marked dulness in appendical region. Operation: the abscess cavity was irrigated and the appendix removed. Death occurred six months later of tuberculosis.

Case XII.—Miss S——, aged twenty-three years, had a third attack June, 1900. Pain and dulness existed in the appendical region. The temperature and pulse were slightly increased. Operation: pus was found and the appendix removed. She recovered with a fistula, which subsequently closed.

Case XIII.—Miss O'D——, aged thirteen years, had an acute attack of two days' duration. Temperature, 103° F.; pulse, 130. Pain and dulness were pronounced. At the operation about two ounces of pus were evacuated and a gangrenous appendix was removed. Recovery.

Case XIV.—M—— was attacked July, 1900, with severe pain in the region of the appendix. These attacks had occurred for the past ten years and had always been thought to be bilious attacks. Temperature, 101° F.; pulse, 100. Pain and dulness in the appendical region were marked. The operation was performed by A. W. Johnstone, of Cincinnati, Ohio. The appendix was perforated and evidence was present that an abscess had emptied itself through the appendix. Recovery.

Case XV.—B——, aged nine years. Temperature, 101° F.; pulse, 115. Pain and dulness were present in the appendical region. At the operation about an ounce of pus was removed. The appendix was not removed on account of firm adhesions. Recovery.

Case XVI.—J. D—— was attacked last July with pain in the region of the appendix, fever, and increased pulse. On account of the patient's large abdomen it was a difficult matter to outline absolute dulness; however, there was a decided flatness in the region of the appendix. The patient seemingly recovered. While visiting in Cleveland, Ohio, pain in the region of the appendix recurred. The operator, Dr. George W. Crile, of Cleveland, reports: "The appendix, omentum, and caput coli were bound together in very firm adhesions. The appendix was found lying down over the brim of the pelvis. It was œdematous, thickened, and very brittle." Recovery.

Case XVII.—F. C——, aged twenty-three years, was admitted to the hospital suffering from an acute attack of appendicitis. Temperature, 102° F.; pulse, 115. Severe pain and marked dulness were present in the appendical region. Operation was performed on December 16, 1900. About a drachm of pus escaped, and the appendix, inflamed and adherent, was removed. Recovery.

Case XVIII.—C. Y——. I was called in the country to see this case on December 28th last. Temperature, 102° F.; pulse, 105. The pain was intense and dulness very marked. Operation was performed the following day. About four ounces of pus escaped; the appendix, found ulcerated and firmly adherent, was not removed. The temperature and pulse fell to normal two days after the operation, and have remained so up to the writing of this paper.

Case XIX.—I was called to see this case by a colleague. There were chills, fever and sweat, and marked pain and dulness in the appendical region. I strongly advised operation, which was as strongly refused; I then offered as the only hope of recovery the emptying of the abscess into the intestine, stating that this was taking a very desperate and almost hopeless chance. I was not a little surprised to learn the following morning that this was just what had happened. There was an immense discharge of pus from the rectum; the temperature and pulse immediately fell to normal, and the case ended in recovery.

Remarks. The foregoing cases show the significance of the formation of dulness. In every instance in which dulness was present pus was diagnosed, and this was verified by either an operation or a post-mortem examination, with the exceptions of Cases I. and XIX. In Case I. the presence of peritonitis with the general septic condition of the patient would lead one to a correct diagnosis; and in Case XIX. the outcome of the case was all that was necessary for a correct conclusion. In Case II. the patient was a laborer, and all attacks were brought on by heavy lifting; a few days' rest, with prompt treatment, would soon dissipate all the symptoms. Case X. is somewhat similar to the one just described, only this instance happened to be in a young lady who had nothing else to do but to attend to her health, and not having to do work of any description, the attacks have seemingly disappeared. Cases I., IV., and VII. would bear me out in the conclusion that the presence of pus is a constant menace, and that an operation is imperative once the diagnosis is made. And this is true, in my opinion, in the remaining cases in which the presence of an actual inflammatory exudate was defined by the presence of dulness.

Chronic Enlargement of the Spleen in Infancy.—John Lovett Morse states that chronic splenic tumor is much more common in infancy than in later years, occurring not only under the same conditions as in

adults, but in many others not associated in them with splenic enlargement. It is an almost constant accompaniment of leukæmia, pseudo-leukæmia, cirrhosis of the liver, and malaria. In malaria the tumor develops early, attains considerable size, and persists a long time. Enlargement of the spleen may occur from amyloid changes. Malignant disease of the spleen in infancy is almost unknown. Most of the chronic affections of infancy cause enlargement of the spleen. All forms of anæmia in infancy may be associated with enlargement of the spleen. The presence or absence of leucocytosis in connection with the anæmia seems to have no direct connection with the size of the spleen. The liver may or may not be enlarged in connection with the splenic enlargement. Of the chronic affections of infancy associated with cachexia, two are especially likely to be associated with splenic enlargement. These are rickets and hereditary syphilis. The writer's experience has shown the comparatively rapid diminution in size of the spleen in anæmia and rickets, with the relief of the causative condition. He is also inclined to think that in hereditary syphilis, too, it usually disappears under treatment.—*Annals of Gynecology and Pediatry*, December, 1900.

Pathogenesis of Gall Stones.—Hugo Summa thus concludes his study of the subject: The causation of gall stones is very manifold. Their formation requires a union of at least two factors. Notwithstanding all our efforts made so far, there are still a number of etiological factors unknown to us. We do not as yet understand the chemical changes in the bile, and the anatomical changes in the gall bladder in various, especially febrile, diseases. One very important group of gall stones is apparently due to the combined effect of temporary impediments in the outflow of bile and lithogenic catarrh of the biliary system. The chief material of these gall stones, cholesterin and lime salts, is not derived from the bile, but from the destruction of the epithelial cells of the mucosa. The pathogenesis of gall stones is still in its infancy.—*St. Louis Medical Review*, December 8, 1900.

The Rational Treatment of Vesical Ulcer.—F. Kreisel endorses the endovesical operation through the cystoscope. It can be performed under local anæsthesia within twenty to forty minutes, according to the extent of the ulceration. Curetting and cauterizing is perfected under the control of the eye, and the manipulations are rendered almost bloodless if care is taken not to carry them over the edges of the ulcer into the adjoining mucous membrane. The patient is up and around the day following the operation, the symptoms subside rapidly, all that remains for a few days is a sensation of soreness in the urethra in the male patient, which is due to the tension of and pressure by the cystoscope, unavoidable on account of the shape of the urethra and the situation of the prostate gland. At the end of the first week shreds representing parts of the eschar appear in the urine, and upon their disappearance within another week the urine becomes clear, and normal conditions regarding the function and capacity of the bladder are restored.—*The Chicago Medical Recorder*, December, 1900.

Case of Lupus Healed under Treatment with Roentgen Rays.—William Allen Pusey reports the case of a woman suffering from lupus, which was extensively situated on the left side of the face and neck, and reached over upon the right side of the chin and upon the right cheek beyond the angle of the mouth. Treatment by exposure to *x*-rays was given with intermissions for about six months, and a cure has resulted. Whether it is a complete cure or not can be determined only by the lapse of time. There remain now, except the scars, no evidences of the disease, and even should more or less recurrence of the lupus take place, the author believes that the results may still be called extraordinary. The only thick scars left are those which were in existence before the treatment began, and these have become less prominent, softer, and more pliable. The scars which have taken the place of the ulcers present when treatment began are soft, thin, flexible, and white, and are as healthy looking as they could possibly be. Finsen's treatment by ultra-violet light probably attains no better results, and in celerity of treatment cannot compare with the *x*-rays.—*The Chicago Medical Recorder*, December, 1900.

The Abortive Treatment of Pneumonia, Catarrhal and Croupous, in Infants and Children.—H. Illoway feels certain that in infants and children the pneumonic process can be arrested at its outset, and more than that, that we have the means and have long had them, wherewith to do it. He proceeds to give a number of histories of his own cases. He has had great success in the use of aconite and veratrum viride. Again in other cases with tumultuous heart action the writer has used digitalis (the infusion or rather decoction) with satisfaction. He believes that the combination of the tincture of aconite root with the tincture of veratrum viride (Norwood's) is the more powerful therapeutic measure, and the one he would resort to preferably. He considers the repetition of the medicine at short intervals a vital factor in the achievement of success.—*Pediatrics*, December 15, 1900.

Oral Sepsis as a Cause of "Septic Gastritis," "Toxic Neuritis," and Other Septic Conditions.—William Hunter says that the condition of the mouth associated with the presence of decayed teeth and rotten fangs is a condition of profound sepsis, differing from ordinary sepsis in that all the pus organisms are continually being swallowed. It is also a sepsis connected with diseased bone. The gastric juice has fortunately a great capacity for killing organisms, but this capacity is not complete in the intervals between food. Cases of gastric catarrh become septic catarrh; septic absorption from teeth and gums must be considerable, and there is also danger of infecting the tonsils, with consequent danger of tonsillitic, pharyngeal, and Eustachian-tube infection. The treatment should consist in removal of diseased stumps and roots, or if that be not possible, in the direct application to each diseased tooth of carbolic acid, one in twenty or one in forty, rubbed in by means of a camel's hair brush or a piece of cotton wool.—*The Practitioner*, December, 1900.

The Human Temperaments and their Application in Medicine.—J. C. Bateson states that by temperaments are understood the states of the body and mind with respect to the predominance of different qualities. A knowledge of temperaments is essential to the physician. According to the Fowler brothers in 1839, the following classification, based upon the three grand anatomical systems of the body, was formulated: (1) The motive or mechanical system. (2) The vital or nutritive system. (3) The mental or nervous system. Corresponding to each there is the motive, vital, and mental temperament. In the motive, there is a superior development of the osseous and muscular systems. The vital is indicative of well-developed digestive organs. The mental is characterized by a frame relatively slight and a head proportionately large. There is great intelligence. Every person has the three primary temperaments in combination, but one or two will generally appear most prominent. When the motive is prominent there is

love of action; capacity for severe and prolonged exertion of mind and body. In the vital there is a fondness for the luxuries of life. In the mental, the brain predominates and shortens life. A knowledge of temperament furnishes a scientific basis for the proper exercise of tact. Idiosyncrasy is a peculiarity of temperament which may be observed to some degree in almost every individual. "One man's meat is another man's poison." These different manifestations are largely due to temperament. If physicians made a study of temperament there would soon be almost a complete cessation of the superstitions and fads of today, for the process of curing would be known to depend on the exercise of the law of healing in accordance with certain conditions of human temperament, and not on some supernatural power.—*Pennsylvania Medical Journal*, December, 1900.

The Bactericidal Power and the Alkalinity of the Blood in Leucocytosis from Intoxication by Mineral Poisons.—A. Bentivegna and F. Carini from the results of experimentation conclude that the presence of leucocytes in cases of mineral poisoning has the same biological significance as that attributed to it in bacterial intoxications and infections, and that the mechanism of defence of the organism acts against mineral toxic substances with the same energies that up to the present time have been considered a special manifestation in the case of bacteria and microbic toxins.—*Lo Sperimentale*, Vol. 54, No. 8.

Abdominal Relaxation a Probable Factor in the Pathogenesis of Gall Stones.—Jesse S. Meyer concludes that: (1) Visceral ptosis consequent upon abdominal relaxation and other causes results in stagnation of the bile through interference with its normal expulsion. (2) The inactivity of the gall bladder and stagnation of the bile predispose the mucous membrane to infection. (3) This infection may be either hæmatogenic through the portal system, etc., or an ascending infection from the duodenum. (4) This results in a catarrhal inflammation of the mucous membrane, an albuminous exudate, and the exfoliation of expithelial cells. (According to Naunyn, the addition of albumin to the bile produces a copious precipitation of the stone-forming elements.) (5) This precipitate, with clumped bacteria and degenerated cell masses as nuclei, forms biliary calculi.—*St. Louis Medical Review*, December 15, 1900.

The Treatment of Acute Inflammation of the Middle Ear.—S. S. Bishop says that in the first stage filling the ear with warmed vaseline and the practice of gentle inflation will suffice to give relief. In the second stage cocaine may be instilled into the ear in eight-per-cent. solution and a full dose of morphine given. Leeches are often of service. Poultices are mischievous. He has seen the following device give great relief. A piece of clean cotton is placed lightly in the mouth of the auditory canal. A pipe is partly filled with tobacco and lighted. Then a piece of thin cloth is placed over the mouth of the pipe-bowl and blown gently through, while the lip-piece of the pipe-stem rests against the cotton pledget. This filters the warm smoke through the cotton into the canal of the ear, and a grateful sedative effect is soon obtained. If, however, pain and bulging of the drumhead continue, paracentesis should be done.—*Laryngoscope*, December, 1900.

The Diplostreptococcus and its Significance in the Etiology of Puerperal Peritonitis.—M. Walthard draws the following conclusions: (1) The diplostreptococcus is a pathogenic germ of the streptococcus group and not a saprophyte. (2) Like the streptococcus pyogenes the diplostreptococcus is found with saprophytic characteristics on dead material, such as the vaginal secretion, the lochia, or the intestinal contents of healthy individuals. (3) The diplostreptococcus is found in pure culture as a producer of inflammation in the diseased tissues of the endometrium and the tubal mucosa, as well as in the exudates of endometritis, salpingitis, oöphoritis, peritonitis, and pericarditis puerperalis. (4) The diplostreptococcus can reach the peritoneum through the endometrium and tubes and produce fatal suppurative inflammation without having entered either the blood or lymph channels. (5) The fatal peritonitis caused by this organism differs from streptococcus peritonitis in its insidious and protracted course, finally ending in the classical picture of diffuse suppurative peritonitis. —*Monatsschrift für Geburtshülfe und Gynäkologie*, December, 1900.

Experiments in the Prophylactic Treatment of Malaria on the Coast of Sardinia.—Raffaele Procaccini gives the results of efforts to suppress malaria among soldiers and sailors who were obliged to work and sleep in districts infected by the disease. In 1895 there were 700 cases of malaria there, in 1899, 113 primary cases and 318 relapses. The prophylactic treatment consisted in protection against the Anopheles mosquito, either by means of locking the men at night into rooms the windows and doors of which were thoroughly screened, or by having them sleep in masks and gloves. The results were unexpectedly brilliant. Among 104 men, there was only one case of malaria, and that in a boy of twelve who had not been sufficiently protected from mosquitos.—*Annali di Medicina Navale*, November-December, 1900.

Neuropathies of the Extremities.—A. Cardarelli enumerates a number of affections, such as torpidity of both hands coming on at night, Raynaud's disease, or swelling and redness of the fingers following shock or chilling, sclerodactylia, Dupuytren's disease or retraction of the palmar aponeurosis, and acromegaly. He believes them to be due, usually, to a functional central lesion. The reasons of the disturbance being so often limited to the extremities, especially the hands, are: 1st, the richness of the nerve supply to the hands; 2d, the fact that when the circulation is disturbed the effect is usually first shown in the extremities; 3d, the fact that the hands are exposed more than other parts to outside irritating agents. The author holds that there are only two forms of treatment which are of use in these cases: electricity, with a constant current along the nerves of the extremities, and massage.—*Rivista Critica di Clinica Medica*, December 15, 1900.

The Intracranial Extirpation of the Gasserian Ganglion without Ligature of the Middle Meningeal Artery.—J. Dollinger sums up his experience as to hemorrhage in the course of extirpation of the Gasserian ganglion, as follows: 1. The Gasserian ganglion can be extirpated without ligature of the middle meningeal artery. This is proved by his five cases. The operation is thereby much shortened, and the complications arising from the ligature are obviated. 2. The anterior division of the artery in half the cases lies in the closed canal of the parietal bone more frequently than in the open sinus, but even then hemorrhage does not in every case occur on turning down the bone flap. 3. With regard to these rare cases of bleeding, we need not previously cut down on the external carotid artery, because, should hemorrhage occur, while compressing the common carotid artery we have plenty of time to plug the foramen spinosum, or, when necessary, to ligature the external carotid artery.—*Medical Press and Circular*, December 19, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, February 9, 1901.

INSECTS AS CONVEYERS OF INFECTION.

WITHIN the past few years the belief has been steadily gaining ground that insects are important factors in the dissemination of various diseases. With regard to the propagation of malaria by the agency of a species of mosquito, the theory to that effect has received striking and conclusive confirmation and is now accepted almost universally. The statement made some considerable time ago, that yellow fever is spread in a similar manner by another species of the same gnat tribe, which would appear to have been further strengthened by the result of the recent experiments in Manila of Drs. Reed, Carrol, and others, may perhaps soon be also accepted as proven. Flies—even before the Spanish-American War—had been under suspicion as carriers of infection, and especially as conveyers of the germs of typhoid fever. Dr. George M. Sternberg had as early as 1885 drawn attention to the necessity of isolating and disinfecting excrement. Many investigators have shown clearly that Asiatic cholera is often transmitted by the agency of flies. Dr. George M. Kober, of Washington, D. C., declared it to be his opinion some years ago that flies played a prominent rôle in transmitting typhoid fever. After the outbreak of the Spanish-American War the opportunities for closely investigating the subject were numerous, and in 1898 Dr. H. A. Veeder published in the MEDICAL RECORD of September 17th an exceptionally able article entitled "Flies as Spreaders of Disease in Camps," adducing a number of strong arguments in support of his contention, that flies are prolific conveyers of typhoid fever when the sanitary arrangements of camps are not properly supervised. These views were practically established by the investigations of the army medical commission, appointed to inquire into the origin and spread of typhoid fever in the United States military camps during the Spanish War, and to the findings of which commission reference has been frequently made in this journal and in other medical journals, both American and foreign. The fact may be taken, therefore, as definitely decided, that flies are responsible for much of the spread of typhoid fever which occurs in military camps and other places where good sanitary arrangements are not sufficiently regarded. Dr. L. O. Howard, of the United States board of agriculture, who has just published a paper on the subject, pertinently points out that, in all the literature dealing with the question, there has been no discrimination made between the different varieties of insects concerned. The word flies is used indifferently by writers, as if all flies were guilty, or as if there was but one kind of fly—presumably the house fly. Dr. Howard accordingly has undertaken a careful investigation of the insect fauna of human excrement, especially of the flies which breed in human fæces or are attracted to them. The result of these researches was exceedingly instructive. It was discovered that the number of species of insects found breeding in or frequenting human excrement was very large, of which the Diptera alone were of significance from the disease-transfer standpoint. The conclusions reached were that it appears plainly that the most abundant species breeding in or attracted to human excrement do not occur in kitchens and dining-rooms; but it is none the less obvious that while the Musca domestica (house fly) under ordinary city and town conditions as they exist at the present day, and more especially in such cities and towns or in such portions of cities as are well cared for and inhabited by a cleanly, respectable population, may not be considered as an imminent source of danger, it is nevertheless under other conditions a factor of the greatest importance in the spread of intestinal disease. It is shown that the house fly prefers horse manure as a breeding-place, but it is also shown that in army camps, where human excrement is left exposed, it will and does breed in this substance in large numbers and may be attracted to it without necessary oviposition. The use of box privies should for similar reasons be abolished, and such a course would, in the opinion of Dr. Howard, tend to diminish the prevalence of typhoid fever. He also advises that boards of health everywhere should look after the proper treatment or disposal of horse manure, primarily in order to reduce the number of house flies to a minimum, and that all regulations regarding the disposal of garbage and foul matter should be made more stringent and should be more strictly enforced. It is a fact that in cleanly towns and localities flies are not generally numerous. By the adoption—in civil communities and in military camps—of as sanitary measures as circumstances will permit, and, above all, by the prompt disposal of garbage and other filth which may be calculated to attract flies, a demonstrated cause of spreading disease will be greatly curtailed.

THE GRAND JURY AND BELLEVUE HOSPITAL.

THE presentment of the grand jury respecting the administration of Bellevue Hospital will be generally received with mingled feelings of gratification and regret. The conviction has long been present in the mind of every one who has given the matter any thought, that all was not as it should have been in Bellevue Hospital, and that a thorough probing of the methods of management prevailing there would result in the public insisting upon a cleansing of its Augean stables. It was also recognized that an investigation by the grand jury would be a beneficial forward movement.

The report issued by the grand jury has to some extent justified this confidence, though many persons, and especially the medical profession as a body, will feel that some of the strictures contained therein are undeservedly harsh and do not cast the blame where it is rightly due. The investigation has clearly proved that gross abuses characterized the management of Bellevue as a whole. It has shown that out of seven hundred insane patients sent from Bellevue to Manhattan Hospital in the year 1900, upward of two hundred and fifty received contusions and bruises upon various parts of the body, and the fact was likewise demonstrated that these injuries, or at any rate the great majority of them, could have been incurred nowhere but at Bellevue. The evidence was too sufficiently plain that the nurses in charge of the insane pavilion were inexperienced in the care of the insane, that there was practically no one to supervise their actions and no expert to instruct them in the performance of their duties. Furthermore, the investigation showed that the methods of restraint in use at Bellevue are out of date and, so far as the mechanical forms are concerned, obsolete; that the books have been kept in a negligent and incompetent way; that appointments are sometimes made through political influence, and not by reason of fitness; and, finally, that the Bellevue Hospital building proper is antiquated and unsuited to modern hospital purposes.

The grand jury has performed a most creditable public service in laying bare the above evils, but the conclusions drawn from these investigations will not altogether meet with the approval of the medical profession nor of those best acquainted with the internal economy of Bellevue Hospital. The grand jury concludes as follows: "It is fairly deducible from the testimony submitted to us that in point of fact the medical board is directly and absolutely responsible for the administration of Bellevue. It has not been made clear to us how this state of affairs has been brought about, but it would appear that it has resulted from the gradual and steady encroachment of that body upon the prerogatives of the commissioner of charities and the superintendent of the institution."

On all hands the fact that the condition of Bellevue is in most respects unsatisfactory and in many absolutely deplorable is freely granted; but that the medical board should be branded as entirely and alone responsible for this unsavory state of affairs is distinctly unfair. Probably, if all were known, it would be found that the reverse of this is the case, and that on more than one occasion the medical board has battled hard to introduce necessary reforms into the administration of Bellevue, but has been overruled by the lay members of the management. Again, it would appear that Dr. Moore was unjustly treated in being summarily dismissed; and that Mr. Keller agreed with the medical board in this opinion was evinced by Dr. Moore's reinstatement, and by the decision of a committee of five from the medical board that the work of caring for patients in the alcoholic and insane wards is too great for one interne. The truth is, that it is the system which is at fault in Bellevue Hospital, and not the commissioner of charities, nor the superintendents, nor the medical board.

If, as before suggested in the MEDICAL RECORD, the municipal hospitals of New York City were to be reformed upon the lines recommended by the charter revision commissioners, there is every reason to hope that friction would be avoided, and that these institutions would be run smoothly and in the best interests of those for whose benefit they were established.

THE ELMIRA REFORMATORY UNDER THE NEW MANAGEMENT.

THE twenty-fifth annual report of the board of managers of the Elmira Reformatory, for the year ending September 30, 1900, has been submitted to the legislature. The gross number of inmates on the books during the past twelve months has been 2,050; of whese 666 were received during that period, and 774 dismissed, producing a daily average of 1,365. The part of the report, however, dealing with the methods of administration will attract the most attention, for the reason that the past year is the first in which the methods pursued by the new board have been in regular working order. The report, commenting upon the situation, says: "The radical differences of view which had existed between the remaining members of the so-called old board and those more recently appointed by Governor Roosevelt, had made harmony of action impossible, and it was not until the beginning of the present year that the latter were able to undertake and enforce the measures for improvement.

"For a number of years tuberculosis has been an increasing and dangerous feature among our prisoners. Many have it upon arrival in a more or less advanced stage; others develop it under the trying conditions of prison life and association with those already affected. The management further became convinced by careful scrutiny, extending over many months, that prisoners, healthy on arrival, became affected." With regard to the medical carelessness of their predecessors, the board declares that there was a marked absence in the preceding medical department of full and detailed records, both as to cases of ordinary disease and those of insanity. Under the head, "Discipline," the report says: "Since the statement in the last annual report, that flogging had been abandoned at Elmira, some sincere friends of the reformatory have expressed the fear that its discipline would deteriorate. The board has not shared this fear. The economic system of the administration has been marked by a serious lack of economy and system. To use a hackneyed phrase, it was saving at the spigot while wasting at the bung-hole. The reformatory has never, to our knowledge, had a steward upon whom was laid the sole responsibility for the purchase of food and materials. There has been no central storehouse and no single storekeeper of full responsibility. The maintenance of the educational system by the present board has been seriously questioned by those who profess to see in the withdrawal of Mr. Brockway the first step toward the destruction of the fabric he has laboriously

created. The board finds in his system much to admire and uphold; something to criticise and modify, and something to condemn."

The notorious phrase, that "new brooms sweep clean," is truer perhaps than many of the much-vaunted axioms that have been handed down to us from our epigrammatic forefathers. It certainly seems, in the case of the Elmira Reformatory, that the present management intends to put the words into practice as far as is possible. To a certain extent, there can be no doubt that the infusion of fresh, vigorous blood to any administrative body has the tendency to quicken the circulation and to impart renewed energy to the whole system. Nothing could be wiser than the remarks of the board with regard to the infection and spread of tuberculosis among prisoners, and any means its members see fit to use in order to stamp out and check this disease will meet with the highest approbation from all grades of society. It is perfectly right, too, that a public institution should be administered as economically as is compatible with the moral and physical well-being of its inmates. The abolition of flogging was probably the result of the public outcry against its continuance, voiced somewhat clamorously by some of the lay journals. If discipline can be properly maintained without flogging, by all means do away with it.

The fact cannot be denied that under Mr. Brockway's rule the Elmira Reformatory took a very high position among such institutions, in the estimation of experienced penologists. The hope is here expressed that the new methods of management may be equally successful in retaining the reformatory in the foremost rank.

THE X-RAYS IN MEDICINE.

The use of the *x*-rays is insufficiently understood by the majority of non-professional men. Some believe that it is possible to see clearly through the twenty-foot wall of an old Norman donjon keep by their aid, while others are quite sceptical as to their efficacy under any circumstances. Dr. Francis H. Williams, of Boston, has an article in the *International Monthly Magazine* in which the powers of the *x*-rays are plainly defined. He says: 1st. They act on a photographic plate like ordinary light. 2d. They excite wonderfully brilliant fluorescence in certain substances which disappear instantly as soon as the *x*-rays are cut off. This property is utilized for medical purposes by means of a fluorescent screen which is made by spreading on a piece of cardboard a thin and even layer of properly made crystals of tungstate of calcium or of platino-cyanide of barium. 3d. These rays pass readily through substances light in weight, such as cardboard, wood, leather, clothing, paper, fat, muscle and skin, but with more difficulty through heavy substances, such as bones and all the heavy metals. This characteristic of the *x*-rays demonstrates that our ideas concerning the transparency of objects must be modified and adapted to the form of radiation under consideration.

The *x*-rays have proved to be of great use in both medicine and surgery, and in no one of either branch more than in tuberculosis. The chief object in this disease is to diagnose tuberculosis as such in the earliest possible stage. This is often an extremely difficult, and in some cases an impossible matter by ordinary means. By the aid of *x*-rays, however, those changes in the organs which are the first signal can be detected in the very beginning of the malady, and thus the patient is able to take the steps necessary successfully to fight the disease before it has gained too strong a hold. The benefits conferred on both the individual and the community at large are plainly of the greatest value. As Dr. Williams says, "The limitations and uses of the *x*-rays not being generally understood, *x*-ray examinations may and probably will be used to play upon the imagination and credulity of patients. To avoid this danger it is well for persons desiring to be examined by the *x*-rays, to bear in mind that, in medical cases, this method must be used by the physician, and in surgical cases its results must be interpreted by a surgeon." The full possibilities of the *x*-rays have not been thoroughly ascertained as yet. There is still a wide field for their intelligent use.

DEATH OF A WELL-KNOWN BRITISH MEDICAL EDITOR.

On Saturday, January 9th, Archibald Hamilton Jacob, B.A., M.D., T.C.D., F.R.C.S.I., died at his residence in Dublin, Ireland. The deceased physician, who was sixty-three years of age, was one of the most widely known and best liked members of the medical profession in Ireland, and had a distinguished career as a practitioner. He took his M.D. degree in 1862, and commenced practice as an ophthalmic surgeon in Dublin, and had for many years occupied the position of professor of ophthalmology in the Royal College of Surgeons, Ireland; he was also at the time of his death oculist to the lord-lieutenant of Ireland, besides holding several hospital posts.

Good, however, as was Dr. Jacob's reputation as a practising physician, his fame as a writer was much more extensive. In 1865 the *Medical Press* of Dublin and the *Medical Circular* of London were amalgamated, and throughout the thirty-five years intervening from that date he has been editor-in-chief and part proprietor of that journal, having succeeded his equally eminent father, Dr. Arthur Jacob, on his retirement.

Dr. Hamilton Jacob, as a writer and reformer, was somewhat of the type of the late Thomas Wakley, the founder of the *Lancet*, being an uncompromising opponent of all sham and jobbery and an ardent supporter of any measure likely to benefit his profession. At the same time his ideas were in a high degree practical, as evidenced by the beneficial alteration effected through his agency in the Irish poor-law medical service and the amelioration he brought about in the situation of the medical poor-law officers of Ireland.

As a writer Dr. Jacob was terse and to the point, and by his judicious conduct in the editorship of the *Medical Press and Circular* he brought that journal to quite the front rank of the medical journals of Great Britain.

He was also a striking example of a man who was able to combine the arduous work of a large public and private practice with the no less trying duties which must necessarily fall upon the shoulders of an editor of a largely circulated journal. Dr. Jacob's qualities in private life were as estimable as those he exhibited in a public capacity; for those who had the pleasure of a personal acquaintance with him say that he was one of the most delightful and intellectual of companions, a clever speaker, a charming *raconteur*, a good musician, and that, over and above these gifts, he possessed a warm and generous heart.

News of the Week.

Dr. Seymour Oppenheimer has been appointed consulting otologist and laryngologist to the Hebrew Sheltering Guardian Society of New York.

No Hearing on Board-of-Health Bill.—The objections to the bill abolishing the present State board of health and establishing a single-headed commission have evidently been satisfied, for the parties that asked for a hearing last week before the Senate commission on public health withdrew their request.

Influenza of Glandular Type in London.—There is said to exist in London at the present time a recrudescence of influenza presenting the distinctive feature of swollen, tender submaxillary glands. No confirmation of this rumor has been received, although this is the season when the ubiquitous malady is wont to make its reappearance.

Mortality Statistics of New York State.—The number of deaths from all causes reported for the year to the State Board of Health is 128,468. This exceeds the mortality of 1899 by 6,647 and the average of the past five years by 8,000. Besides these reported deaths there were 1,600 returned too late for the report, making the death rate for the year 18.5. The increase over last year is largest in the maritime district, where there were 5,600 more deaths than in 1899. Infant mortality was 4,000 greater than last year, but the percentage of deaths under five years of age is the average of the past years.

Discovery of Smallpox Cases.—On Wednesday night, January 30th, and on the following morning, no less than nineteen smallpox cases were found in "Little Italy" between 116th and 125th streets. A raid was made in that district by health inspectors in quest of smallpox and this was the result. No reports of the cases had previously been made. The Italians whose families had been attacked had concealed their sick in order that they might not be sent to the Contagious Diseases' Hospital.

Accidents at the Funeral of the Queen.—There were a number of accidents during the crushes in London on Saturday. Several persons were badly hurt through falling from elevated places. The hospitals cared for thirteen hundred persons who were injured in the crowd; of this number, however, only sixty were seriously hurt, including several policemen and soldiers, and a number of women suffering from broken limbs. The St. John's Ambulance Association attended 1,305 persons injured during the funeral crushes in London. The association had 701 doctors and nurses busy at twenty-six stations.

State Sanatorium for Consumptives in Illinois.—The State board of health of Illinois in its forthcoming biennial report will recommend the building of a State sanatorium for consumptives.

A Tragic Death.—It has transpired that a mechanic was locked in one of the ballast compartments of the steamship *St. Paul* when she was launched five years ago. The skeleton has just been found in the hull of the vessel, which is undergoing repairs.

A Physician Fined for Being Late.—Judge Wiltbank on January 31st imposed a fine of $10 on Dr. William Moore, who was half an hour behind the time named on the subpœna summoning him to appear in court to testify in a case. At first the judge was unwilling to admit the plea of the doctor that he was unavoidably detained by a patient who was seriously ill. Finally, however, the reasonable nature of the excuse was recognized, and the fine was remitted.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy for the week ending February 2, 1901. Medical Inspector W. A. McClurg commissioned a medical inspector, November 19, 1900. Assistant Surgeon H. O. Shiffert ordered to the *Franklin*. Assistant Surgeon E. J. Grow detached from the *Culgoa* and ordered to the *Glacier*, and also to duty at Olongapo, P. I. Pharmacist J. Cowan detached from the *Culgoa* and ordered to the *Glacier*, and also to duty at the Naval Hospital, Cavite, P. I. Passed Assistant Surgeon M. R. Pigott died at Annapolis, Md., January 31, 1901.

To Restrict Sweatshop Work.—An important bill introduced in both branches of the New York legislature on January 30th by Senator Willard and Assemblyman Costello provides that the correct name and address in English of the owner of articles manufactured in tenements shall be attached thereto for the purpose of identification. The name and address must not be taken off until such article is removed. No person not a *bona-fide* member of a family licensed to do work in tenements shall be permitted to labor on such work.

To Prohibit Christian Scientists and Osteopaths from Practising in New York State.—The bill of Assemblyman Hal Bell prohibiting Christian Scientists and osteopaths from practising in this State without the license of a medical practitioner had a hearing on January 30th before the Assembly Committee on Public Health in the Assembly Chamber, which was crowded with more than three hundred Christian Scientists who were there, as one of them expressed it, "to fight the forces of the flesh and the devil." The handful of physicians there to support the measure found themselves outnumbered by 25 to 1.

Honors for Sir William MacCormac. — Sir William MacCormac has received from the President of France the cross of commander of the Legion of Honor.

The British Journal of Tropical Medicine announces that, owing to its increasing circulation and need of more space, two editions will be issued monthly, instead of one as heretofore.

Another Serum.—The *Berliner klinische Wochenschrift*, it is said, ascribes to a physician named Jalz the discovery of an anti-typhoid serum which has been applied successfully in fifty cases. The report adds that the serum is swallowed and not injected.

Illness of the Duke of York.—The Duke of York, who is suffering from an attack of German measles, was unable to attend the Queen's funeral. Sir James Reid and Dr. Laking, who are in attendance, say that the condition of the duke so far is satisfactory.

Dr. Rodermund Captured.—Dr. Mathew J. Rodermund, of Appleton, Wis., the doctor who infected himself with smallpox and then went about exposing others to prove that smallpox is not contagious, was caught by the Milwaukee police as he stepped off the train from Chicago last week. He is now in the Detention Hospital.

The Health of Havana.—The report for the year 1900 of Major W. C. Gorgas, United States army, chief sanitary officer of Havana, was issued recently. Yellow fever claimed 310 victims during the year, while there were 851 deaths from tuberculosis, 506 from diarrhœa and enteritis, 443 from organic heart troubles, 393 from meningitis, 357 from diseases of the arterial system, 344 from malaria, and 319 from pneumonia. There were few deaths from typhoid fever, diphtheria, and smallpox. Of the 1,244 cases of yellow fever which occurred during the year, 920 were in Spaniards and 235 in Americans; about twenty-five per cent. of the Spaniards died and 14.89 per cent. of the Americans.

The Influence of Grippe on the Death Rate is exhibited in the fact that the total number of deaths reported to the Philadelphia bureau of health for the week ending February 2d was 556, being 20 more than for the preceding week and 49 more than for the corresponding week of the preceding year. The most important causes and the number of deaths attributable to them were as follows: Pneumonia, 96; pulmonary tuberculosis, 64; nephritis, 45; disease of the heart, 44; gastro-enteritis, 26; old age, 19. Influenza was itself directly responsible for 20 deaths.

A Home for Trained Nurses.—It should be of especial interest to the medical profession to learn of an entertainment to be given at the Waldorf Astoria Hotel, on the evening of February 16th, by the guild of St. Barnabas for trained nurses. The proceeds will be devoted to securing a house where its members, when not on duty, can find a comfortable home, with a view to their mental, moral, and physical betterment. A number of the leading society women have taken a lively interest in this entertainment. The leading New York hospitals are strongly associated with the guild. Besides the worthiness of its object, this event of the 16th inst. will be most representative from a social and an artistic standpoint. Tickets may be had of Mrs. A. E. Gallant, 60 West Fifty-sixth Street.

Vegetarian Principles Strong in Death.—A rich professor, who died recently in Berlin, left the greater part of his fortune, estimated at 420,000 marks, for the establishment of an orphan asylum where the children should be brought up on strict vegetarian principles.

Anti-Vivisection Bill not to be Taken up this Session.—At a recent meeting of the New England Vivisection Society Joseph L. Greene quoted from Senator Gallinger of New Hampshire to the effect that the bill against cruelty to animals in the District of Columbia would probably not be taken up at the present session because of the pressure of business.

Dr. Emil Muller to Remain at Harlem Hospital.—Dr. Emil Muller, who was the house surgeon at the Harlem Hospital until January 1st last, when he was removed by Commissioner of Charities Keller, has been notified that he has been reappointed. Dr. John F. Blackmar, who had been acting house surgeon since Dr. Muller's removal, will return to his old position of assistant house surgeon.

A Physician's Failure for a Large Amount.—Dr. Francis Auersperg, of 326 West Seventy-eighth street, has, says *The Sun*, filed a petition in bankruptcy with liabilities of $290,729, and no available assets. Nearly all the debts were contracted in Vienna, some in Berlin and Paris, and $1,100 in New York. Dr. Auersperg formerly lived in Vienna and all his property was turned over by the Austrian Bankruptcy Court to Dr. Ignatz Klopetz, of Vienna, on February 29, 1898, and was divided among the creditors.

The State Consumption Hospital Site.—*The Sanitarian* says: "The State forest preserve board and the State board of health have approved the site recommended by the trustees of the State hospital for the treatment of incipient pulmonary tuberculosis. The site, which is located at Raybrook, three miles southeast of Saranac village, contains five hundred and twenty-one acres and will cost the State $7,500. The site selected is on the side of a hill, sloping to the southeast, well sheltered from the prevailing winter winds and facing the picturesque Raybrook Mountain, a mile away. A little to the right of the proposed site is the group of the highest Adirondack Mountains. The top of the hill which commands a beautiful view to the north and west is a plateau which would be admirably adapted, during the summer, for tents in which the male inmates of the hospital could live."

The University of Edinburgh and Advertsiing Testimonials.—The University of Edinburgh has expressed disapproval of the granting of laudatory testimonials of drugs and proprietary remedies by their graduates. It would be well if other institutions of

like standing were to follow a similar course. The custom of well-known physicians allowing their names to be used for advertising purposes is much too prevalent.

Lengthening of the Time for Medical Study in Germany.—A bill has been brought before the federal council of Germany, providing that the time of study for medical students shall be five years instead of the present term of four years and a half.

Typhoid Infection Conveyed by Linen.—Typhoid is spread in various ways. Some few months ago the source of an epidemic on a small scale was traced to infection by means of celery. An unusual mode of conveying the bacilli of the disease has recently been reported from Lambeth (London), England. This locality is inhabited for the most part by the working class, the womenkind of which are in the habit after washing their clothes of sending them to be mangled to the house of a neighbor who possesses a mangling machine. Infected linen thus treated contaminated the mangle, which in turn conveyed the infection to other non-infected clothes.

Crusade against Cigarette Smoking in Michigan.—Five distinct measures have been presented to the legislature of Michigan against the use of cigarettes. Governor Bliss in his inaugural message has championed the anti-cigarette crusade. The bill proposed by Representative Gordon is of a decidedly remarkable nature. It provides for an annual tax of $200 a year upon retailers, and stipulates that they shall purchase cigarettes only in original packages. The bill specifies the dimensions of the packages, which are to be of such an immense size that they will be calculated to restrict the sale of cigarettes to the most prominent dealers.

The American Army in China.—General Chaffee has decided to quarter the troops of the United States in Sibley tents for the Chinese winter. This course was at first sharply criticised by the commandants of the soldiery of the other nations, and the example of the British, Germans, and Japanese, who were housed in deserted Chinese buildings, was pointed to as good examples. But there never were fewer sick men in the American commands, while the German and British hospitals are said to be filled with soldiers. The report goes that the foreign officers have recognized the wisdom of General Chaffee's decision and are borrowing tents from the Americans.

Sing Sing Condemned.—A special committee of the Prison Association, accompanied by Mr. Wingate, an expert sanitary engineer, has been inspecting Sing Sing, and has reported that its insanitary condition is such that it should be demolished. The following are extracts from Mr. Wingate's statement: "The prison was established at Sing Sing in 1834. The buildings are old, obsolete in plan, and have suffered from years of hard usage. Erected at a time when security was the sole object, but little regard was given to the health and comfort of the inmates. The whole aspect of the cell structure is dark, grim, and forbidding, with massive stone walls that drip with moisture in foggy weather and are very chilly in winter, and windows so deep and low that the direct rays of the sun seldom enter. The site of the prison is most unfortunate from a sanitary point of view. The sewage of the village discharges into the Hudson, only a short distance above the prison, and tends to pollute the stream. Where vermin breed so abundantly as to defy whitewash, sulphur fumes, and other destructive agencies, disease germs will also flourish, and no better laboratory for their propagation and diffusion could be devised."

The Astley Cooper Prize.—It is announced that the next triennial prize of £300 ($1,500), under the will of the late Sir Astley F. Cooper, will be awarded to the author of the best treatise on "The Pathology of Carcinoma and the Distribution and Frequency of the Secondary Deposits Corresponding to the Various Primary Growths." The competition is open to the world, with the exception of the staffs of Guy's and St. Thomas' Hospitals and their relations, but the essay must not be the production of two or more authors; and essays, written in English, must be sent to Guy's Hospital, addressed to the physicians and surgeons, on or before January 1, 1904.

Reconstruction of Glasgow Infirmary.—For long serious complaints have been made against the buildings of the Royal Infirmary, Glasgow, and the fact has been recognized that they are not worthy of a city so noted for the riches and public spirit of its citizens. A plan for the reconstruction of the infirmary has now been adopted by the committee appointed to adjudge on the matter. The building is to be constructed in the form of a quadrangle, with a central tower in the front. At the angles will be circular turrets. The building will be divided into three parts—for medical, surgical, and special diseases. The front, or Jubilee Block, is to be six stories in height, and will contain ten large wards and twenty single ones, accommodating two hundred and twenty-five patients. The surgical block will be of the same height, containing eighteen large and twenty-four small wards, with accommodation for two hundred and ninety-six patients. Every block will provide dwelling-accommodation for a resident surgeon. A fine operating-theatre is to be supplied. The roof of the central block will be flat and utilized as a garden. The hospital, when completed, will have room for seven hundred patients.

Year's Records at Bellevue.—The investigation at Bellevue Hospital shows that during the year 1900 24,307 patients were treated in that institution. Of these patients 1,720 died, or 7.076 per cent. of the entire number treated. This percentage really indicates a larger death rate than ordinarily could be charged against the hospital, since it receives from other hospitals a large number of patients who are in a moribund condition upon their arrival. The daily census of Bellevue for the year 1899 shows that the average number of patients under treatment was 690 per day. In the year 1900 the average number of patients treated was 733. In the year 1899 4,081 patients

were treated in the alcoholic ward; in 1900 3,753 patients were treated in this ward. In the male alcoholic ward in 1899 there were 146 deaths; in 1900, 160 deaths. The total number of deaths in the female alcoholic ward for these two years was 81, 46 in 1899, and 35 in 1900. The deaths in the male alcoholic ward in 1899 amounted to 3.577 per cent. Of the number of patients treated in 1900 it was 4.26 per cent. The number of deaths in the female alcoholic ward for 1899 was 2.752 per cent.; for 1900 it was 2.41 per cent. In 1899 1,218 patients were admitted to the pavilion for the male insane; of these patients 29 died. To this same ward in 1900 there were admitted 1,265 patients, while the number of deaths was 40. The number admitted to the pavilion for the female insane in 1899 was 1,049, of which number 17 died, making the death rate 1.62 per cent. In 1900 1,160 patients were treated in this ward and 32 died, making the death rate 2.76 per cent. It is claimed that the medical and surgical wards have been conducted well, and in a manner creditable to the institution, and that the records of these wards compare favorably with those of any hospital in the city.

The Samuel D. Gross Prize.—The trustees of the Samuel D. Gross prize for $1,000, to be given for the best original essay not exceeding one hundred and fifty printed pages, illustrative of some subject in surgical pathology or surgical practice, founded upon original investigations, candidacy being restricted to American citizens, announce that no essay worthy of the prize was received up to January 1, 1901. The essays must be written by a single author, in the English language, and should be sent to the trustees of the Samuel D. Gross prize of the Philadelphia Academy of Surgery, care of College of Physicians, 219 South Thirteenth Street, Philadelphia, on or before October 1, 1901.

Lectures at Columbia College.—The dates and subjects for Dr. Cary N. Cawkins' lectures on "The Protozoa," to be given at Columbia University at 5 P.M., are as follows: February 15th, "The Simplest of Living Animals—General Sketch"; February 19th, "The Sarcode Animals—Naked Bits of Protoplasm"; February 26th, "The Flagellated Organisms the Most Important Group Theoretically of the Protozoa"; March 5th, "Infusoria the Highest Type of the Protozoa"; March 8th, "The Loss of Vitality in Protozoa and its Renewal through Conjugation"; March 12th, "The Protozoon a Physiological Machine."

The Growth of Germany.—The increase of population in Germany is something remarkable. The census is now taken every five years, and reveals the fact that the influx of people from the country to the towns proceeds at a greater rate than ever. The condition of Germany has altered altogether. Fifty or sixty years ago it was mainly an agricultural country; now it may be regarded as essentially an industrial one. Berlin has actually increased in population the most, although relatively several manufacturing centres surpass it. Berlin has 207,000 more inhabitants than at the time of the last census, its population now being 1,884,345; together with the suburbs it contains two and a half millions of people. Nuremberg, in Bavaria, has added to its population within the past five years no fewer than 98,357 souls, the number of persons at present dwelling in the quaint old town reaching the respectable total of 260,743. Posen, in Prussia, exhibits an increase of 58.6 per cent.; its population is now 116,151, 42,912 more than in 1895. Stettin, also in Prussia, has 209,988 inhabitants, an increase of 69,264, and 49.2 per cent. Mannheim on the Rhine has leaped from 97,730 to 160,334, a percentage increase of 43.6. The other large cities taken in order have grown as follows: Hamburg 704,069, increase 79,117; Munich 498,503, increase 87,502; Leipsic 455,120, increase 55,126; Breslau 422,415, increase 49,246; Dresden 395,349, increase 58,909; Cologne 370,685, increase 49,121; Frankfort 287,813, increase 58,531; Chemnitz 206,584, increase 45,567; and Halle, 158,503, increase 40,327.

Philadelphia Neurological Society.—At a stated meeting held January 28th, Dr. Wharton Sinkler read a paper entitled "Paresis, with Symptoms Simulating Brain Tumor." Dr. F. X. Dercum reported "A Case of Brain Tumor, with Hemiplegia, Homonymous Hemianopsia, and Wernicke's Symptom," and exhibited the specimen. Dr. John K. Mitchell reported "A Case of Extensive Endothelioma of the Brain," in which symptoms had existed for many years, and operation was undertaken, but in consequence of the conditions present proved futile. Dr. Charles K. Mills made "Some Remarks on the Localization of Brain Tumors, especially with Reference to the Parietal and Prefrontal Regions, based upon Five Cases in which the Sites of Tumors were Located for the Purpose of Operation." He laid especial stress upon the presence of astereognosis with the preservation of the ordinary forms of sensibility, with or without marked motor phenomena, in the diagnosis of lesions of the superior parietal lobe, and of disturbances in the higher psychic sphere in the diagnosis of lesions of the premotor region. Operation was performed in all of the cases referred to, confirming the diagnosis, and with successful results in three. Dr. D. Riesman exhibited "A Case of Unilateral Oculo-motor Palsy, Probably Due to a Gumma." Dr. Charles K. Mills exhibited a specimen of "Subcortical Brain Tumor," and Dr. W. G. Spiller one of "Diffuse Endothelioma of the Brain." The discussion was participated in by Drs. W. W. Keen, W. J. Taylor, G. E. de Schweinitz, and others. The following officers were elected for the ensuing year: *President*, Dr. James Tyson; *Vice-Presidents*, Drs. C. S. Potts and F. X. Dercum; *Secretary*, Dr. A. A. Eshner; *Treasurer*, Dr. G. Hinsdale; *Councillors*, Drs. D. J. McCarthy, J. Sailer, and W. G. Spiller.

Cheap Gas.—One of the Liverpool papers devoted to the supervision of the gas world in its various bearings, mentions that Dr. Ludwig Mond has invented a process for the production of fuel gas from a cheap form of bituminous coal or slack, and that a bill will be introduced into the next session of the British

parliament for supplying a large district of the midlands with the new agent. The price will not exceed and may even be less than 3*d.* (6 cents) and 4*d.* (8 cents) per thousand feet, according to the quantity taken per quarter, but in any circumstances 4*d.* (8 cents) is to be the maximum price. What a boon it would be to the tenement dwellers of New York if the Consolidated Gas Company of this city were able to avail itself of Dr. Mond's discovery.

The Late Dr. Frank C. Merriam.—The Society of the Alumni of the City Hospital at their last meeting adopted the following preamble and resolutions on the death of their fellow-member, Dr. Frank C. Merriam:

"In the death of Dr. Merriam we lose an esteemed and valued friend, associated with us in the membership of our society for nearly its entire existence. And we desire to acknowledge the mutual friendship and helpfulness we have enjoyed from these years of association. It is, therefore,

"*Resolved*, That we express our sincere and heartfelt sorrow at his death; and that our deepest sympathy be tendered to the doctor's bereaved family. Further, be it

"*Resolved*, That a copy of these resolutions be sent to the family, to the medical journals, and be entered upon the minutes of our society. Adolph Rupp, M.D., A. T. Muzzy, M.D., William L. Stowell, M.D., *Committee.*"

Obituary Notes.—Dr. Charles Burden died suddenly on January 26th, at his residence, 210 East Fifty-second Street.

Dr. Stephen C. Griggs, who had practised medicine for forty-one years in Brooklyn, fell into an open fire-grate on Friday, February 1st, and received fatal injuries. Dr. Griggs, who had been paralyzed for some time, was born in Pomfret, Conn., eighty-two years ago, graduated from Brown University, and studied medicine in New York University. He was prominent in medical charities in Brooklyn.

Dr. Henry F. Barker died at Philadelphia on February 1st, at the age of fifty-seven years. He was a graduate of the medical department of the University of Pennsylvania.

Dr. Nathan Raynor died at Philadelphia on January 25th, of nephritis, at the age of forty-five years. He was graduated from the medical department of the University of Pennsylvania in 1879, and was for two years surgeon on the steamship *Pennsylvania*, plying between Philadelphia and Liverpool.

Dr. Homer O. Jewett, the oldest physician in Cortland County, and well known throughout central New York, died at his home in Cortland on January 30th, aged nearly eighty-two years. Pneumonia was the immediate cause of death. Dr. Jewett was born at Lebanon, Madison County, in 1819. During the winters of 1842 and 1843 he attended the first two courses of lectures delivered in the medical department of the University of New York, and was graduated from that institution in 1843. He had practised in Cortland since 1849. He was a member of the Cortland County Medical Society and one of the founders of the New York State Medical Society. He was also a member of the National Medical Association and the New York Medico-Legal Society. For several years he was vice-president and one of the council of the State Medical Association and president of the third branch of this association.

Progress of Medical Science.

New York Medical Journal, February 2, 1901.

On the Sterilization of Milk; its Advantages and Limitations.—By A. D. Blackader. The paper is a review of some of the salient features of the milk question. The author concludes that milk sterilized by heat is altered to an extent varying according to the elevation of the temperature used in the sterilization and the duration of its exposure, in the following respects: (1) Its proteids are modified and rendered apparently less digestible, but our knowledge on this subject is still indefinite and dependent chiefly on clinical experience; nothing has yet been proved by laboratory experiment. (2) The combination of its saline ingredients with the proteids, a combination which we must admit is not absolutely proved, but which appears to be extremely probable, is more or less broken and the salts assume a condition in which they are less readily absorbed. (3) Natural ferments, whose presence in milk may with much probability be inferred, and which may materially assist its digestion in the infant's stomach, are destroyed. (4) An alteration takes place in the emulsion, normal to milk, which may also have a distinct effect in lessening the digestibility of cow's milk by the infant. Again, it is extremely important that milk after sterilization should be kept at a continuously low temperature, and it is to be remembered that the employment of sterilized milk which has been kept for many days is not free from danger.

Appendicitis in the Female.—By E. W. McRae. The author records the histories of fifteen cases. He believes that the disease is far more common in the female than is generally believed, and that many so-called pelvic inflammations are really appendicitis. This disease usually appears at or about the menstrual epoch, but the pain of appendicitis is more sudden in its onset, and very much more acute than that of pelvic disease. It is frequently accompanied with nausea and sometimes with vomiting; muscular spasm is usually marked in appendicitis, practically absent in beginning pelvic disease. The general disturbance is very much greater, and the progress more rapid in appendicitis than in pelvic disease. An intact hymen argues very strongly for appendicitis. When in doubt, and the symptoms are aggressive, it is much safer to make a diagnosis of appendicitis and operate, than to delay until the case is hopeless.

A Case of Arsenical Dermatitis.—By A. H. Ohmann-Dumesnil. The patient, a Polish woman aged twenty-six years, took "rough on rats" (heaping teaspoonful) with suicidal intent. Prompt treatment saved her life. Two days later she presented on the face a series of vesicles with some pustules. The lips and nose were swollen. A vesicular eruption was present on the buttocks and genitals, but there were no pustules. Subjective symptoms were burning sensation and some itching. The patient was intensely nervous, almost hysterical. Her recovery was uneventful. No new crops of eruption appeared.

A Preliminary Communication, with Projection-Drawings, Illustrating the Topography of the Paracœles (Lateral Ventricles) in their Relations to the Surface of the Cerebrum and the Cranium.—By E. A. Spitzka. This is a study of the brain with special reference to the surgical procedure of tapping or draining the paracœles or lateral ventricles.

Gall Stones and Empyematous Gall Bladders.—By E. Ricketts. This is a discussion of some of the modern surgical measures employed in affections of the gall bladder.

Pharyngeal Adenoids: their Frequency and Sequelæ.—By P. D. Kerrison.

Boston Med. and Surg. Journal, Jan. 24 and 31, 1901.

The Treatment of the Later Phases of Heart Diseases.—John L. Heffron says that by the later phases he means that period of time, short or long, after compensation has once failed. The first indication is to relieve the heart of all extra work, which is best accomplished by rest in the recumbent position, which should be complete. Visitors

who excite emotion should be excluded. Secondly, the volume of blood to be propelled by the heart should be diminished as much as possible. For this purpose the author has found elaterium, calomel, and the salines useful. At the same time the diminution of ingested fluids must be insisted on. Thirdly, the distressing nervousness of the patient, which increases the irritability of a heart already overburdened, must be controlled. Codeine should first be tried in doses of one-half grain hypodermically; if it do not induce sufficient quiet and compel sleep, morphine should be used. When the nervousness is less extreme, gratifying results are obtained from the use of the abstract of cannabis indica, made by Dr. W. M. Smith. The author gives full directions as to diet, and the treatment of various symptoms as they arise.

Retropharyngeal Abscess in the Adult.—J. L. Goodale reports a case, and enumerates the following salient points: (1) It is quite an exceptional disease after the age of four. (2) In regard to classification Bokay distinguishes (*a*) idiopathic abscesses, (*b*) secondary abscesses from diseases of the cervical vertebræ or from the irrigation of pus from a superficial cervical adenitis, (*c*) septic abscesses, (*d*) abscesses from trauma. Bokay suggests giving up the old term "idiopathic," and calling the abscesses coming under this head "retropharyngeal abscesses from retropharyngeal lymphadenitis;" thus separating them from the secondary abscesses, metastatic and traumatic, and permitting at the same time definite etiological knowledge. Bacterial invasion of the lymph glands behind the posterior pharyngeal wall will produce pathological changes in these structures similar to those occurring in other lymphoid tissues, giving rise, however, in view of their localization, to characteristic clinical symptoms.

Peritonsillar Abscess.—F. C. Cobb holds that to abort an attack after peritonsillar swelling has appeared is impossible, and that only the knife can give any relief, the salicylates which are sometimes recommended only contributing to the exhaustion which follows this very debilitating disease. When we find the swelling increasing, our efforts should be directed to bringing the abscess to a head as speedily as possible, by hot-water gargles repeated every half-hour. When the swelling is well under way, the surgeon must incise, using great care. If he fail to find pus in either anterior or posterior pillar, he should enter the supratonsillar fossa, taking care not to penetrate farther backward than the posterior pillar. Should pus be obtained, a wider opening through the tonsil may be secured. Cocaine should be used, either submucously or by application to the mucous membrane, in order to make the procedure as painless as possible.

The Great Toe (Babinski) Phenomenon: a Contribution to the Study of the Normal Plantar Reflex Based on the Observation of One Hundred and Fifty-Six Healthy Individuals.—Morton Prince says that stroking the sole of the foot normally causes a flexion movement, if any, of the toes, particularly the four outer ones. Babinski pointed out that when the motor paths in the cord are diseased, the opposite movement, extension of the toes, especially of the great toe, is caused. From his own experience the author believes that the frequency of the plantar (spinal) reflex, so far as it concerns the toes, has been exaggerated, owing to several sources of fallacy being overlooked, namely: (1) Mistaking the cerebral for the spinal reflex; (2) in stroking the sole it is not difficult by moderate pressure over the first phalanges to cause a purely mechanical flexion of the toe; (3) if the stroke is made from the toe toward the heel, pulling on the skin, when inelastic, will do the same.

A Case of Obliteration of the Right Ureter by a Calcified Fibroid; Removal of Fibroid and Implantation of the Ureter into the Bladder; Recovery.—Maurice H. Richardson describes a case, which he says illustrates some of the dangers of leaving an old fibroid to itself. For several years the patient had suffered from pain in the lower abdomen. A large fluctuating tumor was found, and, under the supposition that it was ovarian, operation was advised. It was found to be a fibroid of the uterus, upon a part of which was a large cyst. It was deeply and broadly attached, the deeper portions on the right side being calcified to a bony hardness. The operation was extremely difficult, the ureter and the bowel being involved. The author followed his plan of making the dissection of the deep pelvis in the full light of day, when every structure can be recognized as the dissection proceeds. The operation was successful, and a good recovery followed.

A Case of Vesical Implantation of the Ureter by Dudley's Forceps Method, after the Failure of Several Plastics.—Edward Reynolds describes in detail an interesting case. The author at one time considered that with the use of Dudley's forceps the grasp of the forceps must necessarily cause sloughing, and thus leave at the point where the ureter enters the bladder a wide gaping slit instead of the normally small orifice. His cystoscopic examination of his own case, however, has convinced him that although the blades of his forceps were apparently tightly closed, there must have been enough nutrition in the portion of the bladder wall between the jaws to enable it to live, thus avoiding a slough, but securing an absolutely firm union of the ureter with the bladder.

A Short Abstract of the Early History of Medicine in Massachusetts to the Year 1800.—By Elbridge G. Cutler.

Pregnancy following Removal of Both Ovaries and Tubes.—By M. A. Morris.

Philadelphia Medical Journal, Jan. 26 and Feb. 2, 1901.

Method for Rapid Elimination of the Gonococcus.—Follen Cabot refers in this paper entirely to the treatment of gonorrhœa in its incipient stage. His method is a compromise between the endoscope and silver nitrate abortive treatment and plain irrigation. He first takes a specimen of the discharge for microscopical examination, then the patient passes urine, after which the urethra is washed out with hot water; then twice a day there is introduced a ten-per-cent. solution of argonin freshly made. An Ultzmann's deep injection syringe or, better still, a rubber bulb holding six drachms is used. The solution is introduced hot, and is kept in the front urethra by pressing the lips of the meatus together as the point of the bulb is withdrawn. By an applicator, a ten-per-cent. solution of argonin is put into the urethra while the solution previously introduced is allowed to flow out. Everything must be done gently and slowly. The solution must be kept in five or ten minutes. If all is going well, the disease remains stationary for two or three days and then subsides. Internally citrate of potash may be given to render the urine bland. The patient should soak the penis in hot water three times daily and should be kept as quiet as possible. If the progress is favorable the strength of the solution may be gradually increased to thirty per cent. An astringent is generally used later. This method the writer believes devoid of danger. All his cases have been satisfactory and, as far as traced, have shown permanent results. The solutions must be freshly prepared each time, and must be hot, 110° to 120° F. The patient must follow the physician's advice implicitly.

Intracranial Hemorrhage in the New-Born.—W. Reynolds Wilson states that intracranial hemorrhage in the newborn is usually the result of rhexis affecting the vessels of the meninges. It is the natural consequence of the traumatism of birth. Meningeal apoplexy, according to Cruveilhier, may be considered the cause of death in one-third of the infants who succumb sub partu or shortly after birth. In the experience of the writer fifteen instances of intracranial hemorrhage were noted in twenty autopsies performed upon the bodies of infants dead within three weeks of birth. The symptom complex is usually as follows: Somnolence, anorexia, digestive disturbances with vomiting (the vomited material sometimes consisting of bloody mucus), piercing, hoarse and fretful cry, contraction or dilatation of the pupils, convulsions. The outcome of the case is usually fatal, death being preceded by a condition of coma. The temperature is variable and irregular. Hyperæsthesia is a marked symptom. The primary object in treatment (Jewett), in hemorrhagic lesions occurring during birth and associated with asphyxia, is to overcome the atelectasis by forced respiration.

Whey-Cream Modifications in Infant Feeding.—Franklin W. White concludes: (1) By the use of whey as a diluent of creams of various strengths, we are able to modify cow's milk so that its proportions of caseinogen and whey proteids will closely correspond to the proportions present in human milk. It is, therefore, rendered far more digestible and suitable for infant feeding. (2) The best temperature for destroying the rennet enzyme in whey is 65.5° C. Whey or whey mixtures should not be heated above 69.3 C., in order to avoid the coagulation of the whey proteids. The percentage of whey proteids in the whey obtained by him was one per cent., while in the analysis of the whole milk, approximately three-quarters of the total proteid was caseinogen and one-quarter was whey proteids. (3) Whey cream mixtures yield a much finer, less bulky, and more digestible coagulum than plain modified mixture with the same total proteids. The coagulum is equalled in fineness only by that of barley-water mixtures. The coagulum yielded by gravity cream mixtures and centrifugal cream mixtures is the same in character.

Scurvy, not Rheumatism.—J. P. Crozer Griffith reports sixteen cases of infantile scurvy. He states that hæmaturia is sometimes the only symptom of scurvy. As to the cause of scurvy, although it seems to be dietetic, yet there is no one dietetic fault which can be held responsible. Oftenest it is found that scorbutic children have been fed upon commercial foods, and there seems reason to believe that these constitute a powerful etiological factor. In some cases the sterilization of milk has seemed to be the cause.

As to symptoms, the affection of the gums is not the earliest symptom generally, and the disease may exist without it. It is usually absent if no teeth have appeared. Pain somewhere, generally in the legs, is oftenest first felt. Treatment is most simple. A proper alteration of the diet, and, even without this, the administration of fresh fruit juices without any change of diet, is sufficient to work a cure which seems almost miraculous.

Retardation of Growth as a Cause of Shortening after Coxitis.—Henry Ling Taylor states that quite unexpectedly to him, and to some extent contrary to his preconceptions this study appears to justify the following conclusions: (1) Considerable retardation of growth, both in length and thickness of the limb and its component bones, is the rule after coxitis and other affections causing long periods of lameness or disability in childhood. (2) The amount of retardation appears to bear a distinct relation to the amount and duration of the restraint or disability. (3) This inhibitory effect of restraint should be considered in selecting treatment for disabling affections of the lower limbs. Other things being equal, locomotion is desirable, and restraint for long periods harmful, though complete or partial interference with function must often be enforced as the least of evils.

Proper Methods of Handling Milk for Infant Feeding.—George Thomas Palmer describes the Trinity Diet Kitchen for Infants, a milk charity in the poor districts of Chicago. He believes the success to be due: First, to the unvarying purity of the milk; second, to the care given to the milk in the kitchen. The rigid instructions given the parents in regard to the handling of the milk, regularity of feeding, and absolute cleanliness have also been factors. The process of separation there carried on permits a uniform quality of milk and removes from it the mucus and slime and occasional blood clots found in all milk. The number of bacteria is considerably decreased. The writer from his experience with pure raw milk is ready to banish forever sterilization or pasteurization of milk.

The Importance of Instruction in Medical Schools on the Modification of Milk for Prescription Feeding.—Andrew H. Whitridge suggests that, at least during the summer months, such of our schools as maintain a high standard of education should appoint qualified men to instruct, by weekly lectures, students and post-graduate physicians in the practical knowledge needed to understand this branch of work. He believes the milk laboratory to be invaluable to all physicians who have infants to feed artificially.

Fatty Degeneration of the Heart.—Thomas E. Satterthwaite concludes: Fatty degeneration of the heart is a common affection, though it is not to be classed as a disease *sui generis*, but rather as a metamorphosis or process attending on loss of compensation in valvular diseases, but also nearly as often on non-valvular diseases. It is caused by fevers, toxæmia, dyscrasias, disorders of nutrition, and mechanical injuries, but it may also be a physiological process; as for example in senility or after parturition. For practical purposes it may be divided into three stages, the first or early, the second or intermediate, and the third or final, and each stage is capable of being distinguished by certain clinical signs. In the early stage the prognosis is best for complete recovery, that is, if the patient does not yield to the primary disease, for in that case he will probably recover with a sound heart, provided the heart complication is properly treated. In the intermediate stage the prognosis is not good for the arrest of the fatty process *in toto*, but the functions of the heart may be so improved that the patient should be able to resume his former work and enjoy a fair degree of health for an indefinite period. In fact we may expect a physiological if not a pathological cure. In the third or final stage, which is marked by such a profound implication of the internal viscera that their functions are in abeyance, the prognosis is always unfavorable. The end will rarely be delayed beyond a few months.

The Tonsils as Portals of Infection.—Julius Ullman concludes: (1) That the normal tonsil has a physiological function, probably protective to the organism. (2) That being in itself often diseased, the physiological function is often impaired and that instead of being protective it is the nidus for the growth of pathogenic organisms and the distribution of their poisonous products into the system. (3) That many grave and fatal general infections have their origin in the tonsils. (4) That, if the exanthemata, especially scarlatina, are of bacterial origin the tonsil acts in part as port of entry. (5) That acute articular rheumatism and the diseases often associated with it, endocarditis and chorea, in a great majority of cases are due to the action of attenuated bacteria, their toxins, or both entering the system through a diseased tonsil. (6) That in rare cases of typhoid fever in which no intestinal ulcerations can be demonstrated, the similarity of the tonsillar tissue and Peyer's patches suggests the portal of entry of the Eberth bacillus to be the tonsil. (7) That scrofulosis is often associated with diseased tonsillar tissue and that the tubercle bacillus often enters the system via the tonsils. (8) That the tonsil is too little examined at necropsy and that much light might be shed on fevers of uncertain origins by bacteriological and histological examination of it.

The Climatic Treatment of Chronic Bright's Disease.—James Tyson and T. Mellor Tyson state that in grouping together large areas we find that the mortality in this disease is highest in the middle Atlantic coast region, next in the north Atlantic, and next in northeastern hills and plateaus, the south Atlantic coast region, and lastly and least, in the southern central region. Reasoning from general principles, we conclude that by far the most important factor in the treatment of chronic Bright's disease is that there should be as little cold, moisture, and variation in temperature as possible. Renal disease is more prevalent in a temperate climate, with ground saturated with moisture, with sudden changes of temperature, and marked difference between the day and night temperatures; less in a cold, and rare in a warm. The conditions of overwork, worry, syphilis, gout, and excessive use of alcohol must also be taken into consideration. Another important agency is the effect of winds, which are very detrimental. Finally, it must not be forgotten that in most of these cases there is a failing heart or one that has already lost compensation. For such cases high altitudes are harmful.

The Climatology of Neurasthenia.—F. Savary Pearce summarizes his article as follows: It is almost axiomatic that an altitude of over two thousand feet is unsuitable for the neurasthenically disposed or convalescent patient. Any very "stimulating" climate should be avoided. Other conditions to be avoided are as follows: Districts menaced by high winds and frequent fogs; cloudy, saturated atmospheres with but slight movements of air currents; low country (sea level) with continuous, non-varying, although moderate heat, as where the effects of the gulf stream are strongly felt. Thus, the Bermuda Islands and Florida are enervating localities. Ideal conditions for the neurasthenic include sea air in a well-wooded country, far enough from the coast to avoid its fogs. A sea voyage is, as a rule, an excellent preliminary to other climatic measures. Provided the voyage is not stormy it acts both psychically and physically in soothing the nervous system. In order to obtain the full benefit of correct climatic conditions the patient must have good food. Without this important adjunct the desirable climatic change may be entirely defeated in its effect on the patient.

A Report of Seven Operations for Brain Tumors and Cysts.—Herm. H. Hoppe states that the following are the conclusions which most authorities have reached on this subject: (1) Tumors of the cortex or subcortical region of

any portion of the cerebral hemispheres which can be reached through the calvarium are operable. (2) If possible the operation should be performed early, when the tumor is small; but even large tumors, and those infiltrating in character, have been operated on with success. (3) Brain surgery is mostly limited to the psychomotor areas (von Bergmann). (4) The result of surgical interference rarely leads to complete recovery. (5) Cerebellar tumors are inoperable. (6) The experience of all writers is against the exploratory operation. (7) Authority is divided as to palliative operations. (8) The writer does not believe that gummata should not be operated upon. He believes that tubercles, if isolated and located so as to be operable, should be operated upon, other things being favorable. Metastatic carcinomata are inoperable.

Report of Two Cases of Afebrile Typhoid.—Charles J. Whalen reports two cases of afebrile typhoid. He adds that ambulatory and afebrile types of the disease must have been very rare or else were not diagnosed in the practice of the older writers.

Influenza Accompanied by Four Distinct Pneumonic Attacks; Otitis Media Purulenta and Cerebral Hyperæmia, Colitis, Inanition, Recovery.—By Julius Ullman.

The Lancet, January 26, 1901.

A Singular Case of Extensive Deposit of Phosphate of Lime in the Lungs.—By T. Fisher. The patient was a woman aged thirty-two, who died of pneumonia. Autopsy showed both lungs studded with granules like sand, which adhered to the finger when it was rubbed over the pulmonary tissue. These granules contained about seventy-five per cent. of lime phosphate. No cause for this peculiar condition could be assigned either from the woman's occupation or from the taking of medicines containing phosphates. Although the author could detect in these little nodules nothing like a nucleus, he is inclined to think that they were started by numerous localized areas of irritation. The condition probably originated in the invasion of the lungs by some microbe of low virulence.

A Suggested Method of Preventing Water-Borne Enteric Fever amongst Armies in the Field.—By L. C. Parkes. This method consists in the addition to drinking-water of an antiseptic, namely, sodium bisulphate, which is to be carried by soldiers in the shape of gr. v. tabloids, one of which will render potable about four ounces of drinking-water. It should be dissolved fifteen minutes before the water is used. The principle of this method is obvious. Its efficacy is predicated upon a carefully conducted series of bacteriological experiments. The acid tabloids are also of service in preventing thirst and render the water much more effectual in slaking thirst. They promote the flow of saliva and prevent parching of the mouth.

Removal of a Foreign Body from the Bronchus by Intrathoracic Tracheotomy.—By H. Milton. The patient was a man of forty, who had worn a silver tracheotomy tube inserted for laryngeal stenosis due to syphilis. The tubular portion of the outer silver tube had become detached from the shield and had fallen into the trachea. It was impossible to recover it by the usual devices, and finally the sternum was split from top to bottom, the halves were pried apart, and an incision was made in the trachea 2 cm. above the bifurcation. Through this opening the tube was removed. The patient died of heart failure twenty-four hours later.

Notes on a Case of Poisoning by Coal-Tar Naphtha.—A girl aged five years took an undetermined quantity of the naphtha and soon became comatose. Her face was dusky, the pupils were dilated, the conjunctivæ insensitive, and the pulse was small and rapid. A strong benzin odor was given off from the body. Emetics were given, hot foot-baths were used, and artificial respiration was practised for some time. After some ninety minutes of hard work the child regained consciousness and began to cry. Two days later a general bronchitis set in and the child died eight days after taking the poison.

Spleno-Medullary Leukæmia; Remarkable Toleration of Arsenic.—By C. Heaton. A patient was under treatment for two hundred and seventy-one days, during which time, including intervals amounting to fifty-eight days, he took hypodermatically the following amounts of arsenic. Arsenious acid 5½ grains, arseniate of sodium 105 grains, and sodium cacodylate 10⅔ grains. In addition, 10⅔ grains of sodium cacodylate were administered orally. The maximum dose administered at one time was 2⅔ grains of arseniate of sodium, equivalent to 4 drachms 26 minims of liquor sodii arseniatis.

Results of Thirty-five Prophylactic Injections of the Anti-Diphtheritic Serum.—By P. R. Blake.

British Medical Journal, January 26, 1901.

Preliminary Note on an Unclassified Type of West African Fever.—S. W. Thompstone, R. A. Bennett, and H. E. Annett sum up the following points, which serve to differentiate this type of fever from others occurring on the West African coast, and further negative its connection with true malarial fever: (1) These cases occur during the dry season, at a time when the number of typical cases of malarial fever is smallest. (2) The onset, symptoms, and course of the disease are quite atypical of malarial fever; for example, the absence of rigors, of shivering, of the hot and cold stages, of vomiting, of enlarged spleen, etc. (3) The continued tendency to hyperpyrexia, only checked by cold baths, the temperature being easily brought to normal, and then creeping up again directly the cold applications are stopped. (4) After the hyperpyrexial stage, the very long period during which the temperature is continually above the normal, varying during the day not more than one degree, and falling by very prolonged lysis. (5) No drugs, including quinine and phenacetin, appear to produce any effect on the course of the disease. (6) Absence of hæmamœbæ and of pigmented leucocytes. (7) The peculiar tendency of the blood to rapid coagulation and its comparative richness in red corpuscles and hæmoglobin.

Summary of Researches on the Propagation of Malaria in British Central Africa.—C. W. Daniels states that no method for the prevention of the propagation of malaria is or can be of general application to the exclusion of others. A combination of methods strictly in accordance with local conditions promises the best results. The greatest difficulty will probably result from the scepticism with which the subject will be met in the tropics. Sufficient regard to the species of Anopheles has not been paid in describing their habits and breeding-places. The very local distribution of some of the species indicates some important differences as yet unknown. The writer believes that it is requisite for each species of Anopheles that direct proof should be obtained whether the human malarial parasites develop in it or not. In only a few is the proof at present conclusive, and it is probably being too hastily assumed that the whole genus is implicated.

Remarks on the Apparent Immunity of Asiatics from Enteric Fever.—Francis W. Clark gives the following table to show the apparent immunity of Asiatics from enteric fever:

	1890	1891.	1892	1893.	1894	1895	1896	1897.	1898.	1899.	Total.
Chinese	1	5	..	..	2	10	7	1	9	16	51
Non-Chinese	4	5	..	5	4	5	7	10	14	11	65

During the ten years, 1890–99, only fifty-one deaths of Chinese from enteric fever were registered, as against sixty-five deaths of non-Chinese, although the Chinese form ninety-four per cent. of the total population.

Veld Sores.—J. W. Pridmore has made the following observations: (1) In the cold weather and at high altitudes the horse tick is rarely found, and there is coincident with this a disappearance of veld sores. (2) Veld sores are more common in the cavalry and artillery ranks than in the infantry regiments, in which case they are mainly confined to batmen and grooms. (3) There is, so far as his experience goes, a complete immunity amongst officers, who naturally do not groom their own horses. (4) From the character of the sore it would appear to be of a specific bacterial origin and not a simple ulcer following on an ordinary abrasion and aggravated by the presence of the ordinary putrefactive germs. This is evidenced by its marked tendency to spread, and at times the slowness with which it heals under treatment.

Observations on the Character of the Cells in the Exudation in Acute Interstitial Nephritis, with Special Reference to the Presence of Cells with Eosinophilic Granulations.—W. T. Howard, Jr., states that the cells in acute interstitial nephritis have been described by various authors as "lymphoid cells," "small round-cell infiltration," "leucocytes," and have been thought to have their origin in (1) the blood-vessels (emigration), (2) proliferation of the vascular endothelium, (3) from the fixed connective-tissue cells of the part. These cells are derived from the blood-vessels, whence they emigrate into the interstitial tissue. The writer concludes that he has been able to confirm Councilman's observations of the occurrence (1) of plasma cells, lymphocytes, polymorphonuclear leucocytes in acute interstitial nephritis. (2) The presence of lymphocyte and plasma cells in the dilated vessels. (3) Mitosis and evident amœboid activity of plasma cells in both blood-vessels and tissues. The writer, in addition to the cells described by previous authors, finds large numbers of typical eosinophilic leucocytes in the interstitial exudation and in the blood-vessels in acute interstitial nephritis. In some places in one case these were the most numerous cells in the exudation. The eosinophilic leucocytes in the lesions of acute interstitial nephritis are for the most part brought to the part by the blood-vessels and reach the interstitial tissue by emigration, but there is evidence (in one case) that they may be formed locally from plasma cells. The large phagocytic cells were not found in the writer's cases.

A Clinical Study of Diphtheria.—Fred Grant Burrows calls attention to the difference in the clinical picture of a case of diphtheria properly treated with antitoxin and one as it was treated three or four years ago. From being the most fatal of the acute infectious diseases, with a death rate of from thirty to fifty per cent., its mortality has been lowered to such an extent that it is now but a little more important factor in the total death rate of Boston than typhoid fever. Of 1,962 uncomplicated cases 947 were in males and 1,015 were in females. There was no appreciable difference in the death rate of the sexes. A study of the distribution of the membrane shows that in a majority of the cases it was on both tonsils and often elsewhere in addition. About sixty-five per cent. of the cases had some form of cardiac disturbance at some time during the progress of the disease. Cases treated by the free use of antitoxin—early and with large doses—do not have albuminuria at any period of the disease. In the 1,962 cases there were 337 cases of laryngeal stenosis. Experience gained from treating this series of 1,962 cases, as well as others, leads to the conviction that primary tracheotomy no longer has a place in the treatment of simple diphtheritic laryngeal stenosis. Alcoholic stimulation in diphtheria is most valuable. Early diagnosis and prompt treatment are most essential. The toxin of the disease can be neutralized best by giving antitoxin early, in large doses, and at frequent intervals. Continued and prolonged rest in bed is necessary. The various complications demand an untiring vigilance.

Refractory Syphilis, with Report of a Case Utterly Resistant to Specific Treatment.—Jay F. Schamberg reports this case of a woman aged thirty-nine years. The patient has been most carefully treated with the specifics for this disease, but they have failed to exert any pronounced influence either upon the disease or upon the existing syphilitic lesions. Local treatment has been used almost constantly, an ointment of calomel and carbolic acid having been found to give the best results.

Intestinal Perforation Occurring in Enteric Fever and its Treatment, with Notes of Two Cases.—By W. Taylor. Case I. was that of a woman who had convalesced from an attack of typhoid. Symptoms of intestinal obstruction developed and the abdomen was opened. A suppurating right ovary was discovered, but the condition of the patient rendered it impossible to do anything else than dry out all the pus. The patient seemed to make a good recovery in a surgical way, though she seemed to have a relapse of the typhoid. Fifteen days later the abdominal symptoms again appeared, and it was thought that pus had reaccumulated in the pelvis. The lower portion of the original incision was reopened and a perforation about half an inch long was discovered extending along the floor of the ulcer from which several drachms of fecal matter had escaped. The abdomen was again cleansed and sutured, and a gauze drain left in the wound. The patient did well for a while, but died fifteen days after the second operation. Autopsy showed a perforation almost an inch from the one sutured, the latter having apparently healed. The remarkable point is that union followed suture of so diseased an intestine in a patient so exhausted by fever and suppuration, and that at so advanced a stage as the sixty-fourth day after her enteric fever first began. Case II. was that of a woman aged twenty-eight years, who perforated in the fifth week of her fever. Operation was performed, but she died in six hours. The article closes with general remarks and statistics.

Surgery as a Science and an Art.—By C. Y. Pearson.

Chloride of Calcium.—By Ninian Falkiner.

French Journals.

Albumosuria of Bence-Jones and Albumose Urines.—Hugounenq defines albumoses as intermediary products between the albumins and the peptones. They appear in the urine in a great number of cases, which may fall into two distinct classes: (1) The albumosuria of Bence-Jones is characterized by the fact that when the urine is heated, without the addition of anything, it coagulates at about 60° and becomes clear by boiling, on account of the partial or total solution of the precipitate. This albumosuria, elsewhere very rare (there are scarcely more than a dozen reports), is connected most often, if not always, with lesions of the bones (osteomalacia, for example). (2) The ordinary albumosuria, otherwise like that just described, does not present the characteristic sign of the former. It is often found in connection with the existence of nephritis, but can also be independent of it.—*Lyon Médical*, January 20, 1901.

Alimentary Stasis and Right Lateral Decubitus.—Alfred Martinet states that the causes of alimentary stasis are numerous and its occurrence is most frequent. Various symptoms of "indigestion" are present. In all cases of this trouble, when the cause is not a permanent mechanical obstacle or an organic lesion, *e.g.*, a cancer of the pylorus, the following measures will often give most satisfactory results. About a quarter to a half hour after eating let the patient, as soon as feelings of discomfort supervene, stretch himself on a bed or couch, lie on the right side with the head slightly raised, and in this position drink a cup of hot camomile tea. The pylorus is thus placed in the most favorable position, the fluid warms the parts, overcomes the pyloric spasm, corrects the acidity of the stomach, and generally the results of this proceeding are most happy.—*La Presse Médicale*, January 2, 1901.

Normal Temperature of the Human Body.—Borde has performed much experimental work on this subject, from which he believes the rectal temperature of the adult in good health to be 36.7°. When the temperature exceeded this point, it generally seemed attributable to muscular exercise or to intellectual work. As to whether the child has the same rectal temperature as the adult, the writer from his careful researches has reached an affirmative conclusion, *i.e.*, the child has a temperature of about 36.7° if it is in repose and normally clothed.—*Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, January 20, 1901.

Fibroma and Pregnancy.—C. Jacobs, after reporting three cases of this nature, states that the problem presented to the physician by this condition is always very grave. The writer believes that after very careful examination of the patient, if the physician is convinced that the tumor or tumors so obstruct the pelvis as to render natural expulsion of the child impossible, he should counsel intervention. When, however, pregnancy has arrived at term, or when labor has begun, the problem becomes still more serious and demands an immediate decision.—*Le Progrès Médical*, January 15, 1901.

Total Abdominal Hysterectomy in Cases of Dystocia from Uterine Fibromata.—G. Eustache states that total abdomi-

nal hysterectomy performed most carefully is not difficult of execution and has given happy results. It is the operation of choice in cases of dystocia from uterine fibromata, pregnancy being at term. Under this title it ought hereafter to be inscribed in the list of obstetrical operations.—*Journal des Sciences Médicales de Lille*, January, 1901.

Berliner klinische Wochenschrift, No. 2, Jan. 14, 1901.

Succussion of the Kidneys.—By S. Goldflam. This is a procedure to determine whether the kidneys are sensitive or not. The patient stands or sits with the back toward the examiner, while the upper part of the body is bared and slightly bent forward. With the ulnar side of the closed fist the examiner gives slight blows either vertically to the mass of the lumbo-sacral muscles or obliquely: there ensues a trembling of the region which in healthy persons is entirely free from pain, but which in many kidney lesions causes sensations similar to those resulting from palpation and ballottement. This method is not applicable to all kidney lesions, and is to be looked upon merely as a supplemental means of diagnosis.

Deutsche medicinische Wochenschrift, Jan. 17, 1901.

Vaginal and Abdominal Incision in Tuberculous Peritonitis.—A. Baumgart, basing his conclusions on the statistics of thirty-six operative cases, considers that entry of the abdomen by the vaginal route is to be favorably compared with the older method of operation. The true *rationale* of the undoubtedly beneficial effects following laparotomy in this disease is still unexplained and *a priori* there is no reason for assuming that incision through the vaginal vault is less efficacious than elsewhere. The advantages are that shock is less and convalescence more speedy, while the danger of infection also is not so great as that accompanying laparotomy. Colpocœliotomy offers equal opportunities for the removal of diseased appendages. If laparotomy is performed, a small incision in the linea alba is preferable to a long one. Rectal examination affords a valuable means of confirming the diagnosis, and is also of service in observing the course of the disease after operation. Both tuberculous ascites and the dry form of the malady are susceptible of operative cure.

A New Delicate Sugar Reaction.—E. Riegler describes a new phenyl hydrazin reaction said to be of great delicacy. Twenty drops of urine are placed in a watch glass and a knife point of white pure phenyl hydrazin hydrochlorate, a somewhat larger amount of sodium acetate, and forty drops of water are added. The mixture is brought to a boil over an alcohol lamp and then shaken with two and a half drachms of ten-per-cent. caustic soda solution. If sugar is present in amounts over 0.1 per cent., a reddish-violet color will appear in a few seconds. It is to be noted that the color is to be observed by transmitted light, that the whole fluid and not a possible precipitate of phosphates alone must be colored, and that the coloration should appear within five minutes, as even normal urine may give it after this length of time has elapsed.

Contributions to the Study of Kidney Function.—By L. Lipman-Wulf.

A Case of Cured Hydrocephalus.—By H. Neumann.

Münchener med. Wochenschrift, Jan. 8 and 15, 1901.

Subcutaneous Laceration of the Spleen and its Operative Treatment.—Jordan reports a case in which this formidable casualty was successfully treated by extirpation of the injured organ. The patient was a cavalry officer who was thrown from his horse in such a way that the hilt of his sword was forced into his left side below the free costal border. After a short time he was able to get up and walk, but soon collapsed and in the next few hours the classical picture of concealed hemorrhage was presented. Laparotomy in the left semilunar line eight hours after reception of the injury corroborated the diagnosis made of rupture of the spleen and revealed the abdomen filled with fresh and coagulated blood. This was removed, the vertical incision extended by a transverse cut, and the spleen removed after ligature of its pedicle. The abdominal cavity was then cleansed of blood clots and the wound completely closed. The patient was almost pulseless when brought on the table, but under repeated infusion, carried out while the operation was in progress, rallied somewhat, and left the operating-room in better condition than he entered it. Convalescence was protracted by various complications, but finally the patient recovered completely, and now, seven months after the accident, seems well in every way and apparently has not suffered through the removal of the organ. Two months after operation the hæmoglobin was fifty per cent. and the red blood cells numbered 2,800,000; leucocytes, 2,800. Now the corresponding figures are seventy-five to eighty per cent. and 4,400,000, while the white cells are only slightly increased.

Steam Disinfection in Surgery.—E. Braatz suggests that in spite of the common belief that all further advance in surgical sterilization is to be sought in more efficient methods of hand disinfection, even the apparent simple technique of sterilizing dressings is open to improvement. After even three-quarters of an hour's sojourn in a well-constructed sterilizer it was found by a specially devised electric annunciator that the temperature in the centre of a package of gauze enclosed in the usual container had not risen above 96° C., so that the asepsis of the dressing could not by any means be assumed. It was furthermore determined that a preliminary heating by dry air, which is a part of the process in many apparatuses which have costly appliances for making this possible, far from being an advantage as supposed, is actually a drawback. Steam at 100° entering a roll of material which had previously been heated to 89 developed a temperature of 122°. Rubner has shown by actual experiment that spores of bacteria which perished in six minutes in steam at a temperature of 99.8° survived thirty minutes in superheated steam at 124° to 126°. The conclusion drawn, therefore, is that such preliminary heating is not only a troublesome procedure, increasing the cost of the apparatus, but even directly defeats the object it is intended to serve.

The Effect of Subcutaneous Gelatin Injection on Renal Hemorrhage.—Gossner reports a case in which seemingly uncontrollable internal hemorrhage was permanently checked by the hypodermic use of gelatin solution. The patient had for several months been voiding urine containing large amounts of blood, which on cystoscopic examination was found to come from one ureter. The diagnosis of a hemorrhagic pyelitis was made and the usual course of hæmostatic treatment with ergotin, chloride of iron, lead acetate, and tannin resorted to without avail. Finally, 200 c.c. of 2.5-per-cent. sterile gelatin solution were injected into the subcutaneous tissue of the chest. Contrary to the observations of most writers, severe pain and general disturbances, headache, vertigo, etc., were experienced, but the result was proportional to the discomfort; for the very next morning the urine was free from blood and has continued so for three months.

Progressive Diphtheria with Early Serum Therapy.—Trumpp reports a case of laryngeal diphtheria which terminated fatally in spite of intubation, tracheotomy, and the injection of six thousand antitoxin units. Inasmuch as the case ran much the same course as was commonly observed in the ante-serum days and the remedy appeared to have been wholly without effect on the severity of the disease, the author has endeavored to find some cause for the somewhat unusual lack of response to treatment. After careful analysis and the exclusion of other possible factors he ascribes the lack of efficacy of the serum to its not being so fresh as is usually considered advisable to use. Inasmuch as nothing definite has as yet been established concerning the keeping qualities of the serum, this is an interesting question and deserves further investigation.

Free Ducts in Gall-Stone Operations.—F. Kuhn emphasizes the necessity for a thorough and careful search for hidden stones and obstructions in the ducts before terminating a gall-bladder operation. Many of the so-called relapses after operation are doubtless due to oversight in this respect, and the author cites a case in which a second operation performed for what apparently was a recurrence revealed a single large facetted stone which evidently had been overlooked. In another instance a fibrous stenosis of the common duct near the duodenum produced typical obstructive symptoms which were completely relieved by a cholecystenterostomy.

Archives Générales de Médecine, January, 1901.

Early Exploratory Laparotomy for Intestinal Perforation during the Course of Typhoid Fever.—Harvey Cushing performs this operation under cocaine (general anæsthesia being contraindicated in typhoid), using Schleich's infiltration process. The incision made is the same as in appendectomy. Surgical treatment of intestinal lesions will present no difficulty to the experienced laparotomist. The question of drainage is of importance, and its use will depend upon the condition of the intestine in the vicinity of the perforation. Should the Peyer's patches seem on the verge of perforation it would be wise to place a drainage tube near them. The author describes the symptoms of the preperforative stage. Out of eleven cases operated on in the Johns Hopkins Hospital the lives of five were saved by means of the operation.

Werlhof's Infection, and its Cure by Means of Intravenous Injections of Mercury Bichloride.—Arnaldo Lusignoli concludes his article as follows: Hemorrhagic diseases (scorbutus, Werlhof's infection, purpura) are due to a specific micro-organism, whose products penetrate into the circulatory blood. These diseases are of the same nature, differing only in the intensity of their manifestation. Mercury bichloride given intravenously cures the patients. The author uses from 0.001 gm. to 0.003 gm. a day.

Impaired Thermic Sensibility in Hemiplegia.—P. Chatin says that in certain cases of hemiplegia of cerebral origin, there may be a delayed perception of certain sensations, especially that of heat. Not only may the sensation of heat be perceived tardily, but it may even be mistaken for a sensation of cold. The author concludes that the impairment is central, cerebral, consisting of lesions in the internal capsule, the optic thalamus, and even of the cortex.

Four Cases of Mental Torticollis.—E. Feindel and Henry Meige report four cases of this singular affection, which is characterized by a malposition of the head and neck, which may be permanent or intermittent and which the patient can correct by some special manœuvre, as the pressure of a finger on the chin, holding the head with both hands, etc.

The Treatment of Fractures of the Patella by "Cerclage."—By P. A. Cassedebat.

Alexis Boyer (1757–1833).—By P. Tillaux.

Reviews and Notices.

Modern Surgery, General and Operative. By John Chalmers Da Costa, M.D., Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia; Surgeon to the Philadelphia Hospital and to St. Joseph's Hospital, Philadelphia. With four hundred and ninety-three Illustrations. Third Edition, Revised and Enlarged. Philadelphia and London: W. B. Saunders & Co. 1900, pp. 1117.

The third edition of this work follows the general lines of its predecessors, but differs mainly in the addition of much new information and alterations in the old text. Throughout the author has aimed to instruct the reader in a practical manner, omitting what modern surgery has discarded and retaining what at present are the accepted methods in the great surgical centres. Special attention has been accorded to fractures and dislocations and to the main surgical operations. The arrangement is excellent and the illustrations are selected for their usefulness.

A Text-Book of Pathology. By Alfred Stengel, M.D., Professor of Clinical Medicine in the University of Pennsylvania; Physician to the Philadelphia Hospital; Physician to the Children's Hospital, Philadelphia, etc. With three hundred and seventy-two illustrations. Third Edition, Revised. Philadelphia and London: W. B. Saunders & Co. 1900, pp. 873. Cloth, $5; half morocco $6.

In this new and revised edition the author has improved a work already excellent, having incorporated all that is new and important which pertains to the subject in hand. Special praise should be bestowed upon the excellent illustrations, many of them in colors, and to the clearness of the text. The author has trusted Dr. Joseph Sailer with the revision of the sections on the pathology of the nervous system, which maintains the high standard which exists throughout the book.

Malaria, According to the New Researches. By Prof. Angelo Celli, Director of the Institute of Hygiene, University of Rome. Translated from the Second Italian Edition by John Joseph Eyre, M.R.C.P., L.R.C.S. Ire., D.P.H., Cambridge. With an Introduction by Dr. Patrick Manson, Medical Adviser to the Colonial Office. With maps and illustrations. London, New York, and Bombay: Longmans, Green & Co. 1900.

This is a very interesting presentation of the subject of malaria as we know it to-day, at least as it occurs in the Roman Campagna. Naturally the agency of mosquitos in the spread of the disease and the practical deductions from this fact receive special attention. The discussion on the prophylaxis of malaria is most interesting, but, unfortunately, the whole question is still in such a chaotic state that no definite rules can be laid down beyond that of keeping off the night mosquitos by window and door screens and by mosquito netting around the bed. Much of the book is taken up with a discussion of the special conditions prevailing in the Campagna and of the means best adapted for their improvement. There is a very complete bibliography of Roman malaria.

Experimental Research into the Surgery of the Respiratory System. By George W. Crile, A.M., M.D., Ph.D., etc. Second Edition. Philadelphia: J. B. Lippincott Company. 1900.

This volume contains the results of many painstaking and extensive experiments on animals with reference to surgical work upon the respiratory apparatus. The work is almost entirely devoted to the immediate results of the experiments, and not much space is given to the bearing of this sort of experimentation upon surgery in the case of the human being. The book contains more of interest to the physiologist than to the surgeon.

The Care of the Consumptive. By Charles Fox Gardiner, M.D., Non-Resident Fellow of the New York Academy of Medicine. New York and London: G. P. Putnam's Sons. 1900.

In this book of some one hundred and seventy pages the writer has set forth in a very clear and practical way certain general rules that should govern the consumptives in the use of the natural therapeutic agencies—fresh air, sunlight, food, rest, and exercise—so that they may be employed to the best advantage. He has compiled in a very short space and in an interesting narrative style many valuable facts that have been verified by his own practical experience. Technical terms are conspicuous by their absence. This will make the book all the more useful to that great majority of consumptives who are unable to avail themselves of the advantages offered by the leading sanatoria of our country. The chapters on out-door life, food, and exercise are particularly instructive. In all of these the writer emphasizes the importance of making the individual condition of each case the index to the kind of remedy and the amount to be applied. The chapters on Colorado Springs will be specially valuable to physicians as well as patients who have not visited Colorado. The book is well written and well edited.

Stringtown on the Pike: A Tale of Northernmost Kentucky. By John Uri Lloyd, Author of "Etidorhpa," etc. With illustrations. New York: Dodd, Mead & Company. 1901.

This volume represents a different kind of fiction from what we are accustomed to review occasionally. It is a somewhat melodramatic tale involving a Kentucky feud with very radical results, a mixture of West African voodooism and superstition, a heroine deprived of her name by an insensate father, and a chemist who is compelled by the exigencies of the plot to neglect precautions, in looking for strychnine in the stomach of an alleged victim of poison, which could not possibly be overlooked by a student, much less by the defence in a murder trial, in order that he may afterward be confuted by the heroine, who then feels it necessary to renounce him and retire into a convent. The book is, however, interesting and dramatic, though the narrative is somewhat disjointed, and several of the characters have the hall-marks of genuineness. The old negro speaks a good dialect, but we think that he would have come to grief very soon in his interference in the affairs of white people in real life, and would not have been allowed to see the fulfilment of the prophecies of his polished stone.

A Clinical Treatise on Fractures. By William Barton Hopkins, M.D., Surgeon to the Pennsylvania Hospital, etc. Philadelphia: J. B. Lippincott Company. 1900.

This volume is a very handsome addition to the literature of its subject. The author has set out to write a clinical treatise, which must naturally rest largely on personal experience, and he has used his own clinical lectures at the

Pennsylvania Hospital as a ground work. Old and discarded methods of treatment, and pathological ideas which have been abandoned, have been omitted, and most attention has been devoted to those methods of treatment which have proved most satisfactory to the author. The illustrations throughout the book are new and excellent, and many of them are very satisfactory skiagrams. A series of experiments to ascertain the breaking strain in bones under varying circumstances is described in the introduction, and then the chapters are devoted to a systematic account of fractures, first as occurring in the extremities, and then those of the trunk and head. There are very few illustrations showing methods of treatment, for the exposition of which the author depends upon descriptions. The pages devoted to fractures of the skull and their complications afford an interesting and concise discussion of the subject, chiefly upon the operative aspect of the question. The last pages are devoted to the subject of compound fractures and ununited or incompletely united fractures, all of which are discussed in a thoroughly sound way. The author's remarks upon bone-joining are very interesting, and his descriptions of the formation of the joining and the preparation and use of the ivory screw should be read by all interested in the subject.

Medical and Surgical Report of the Presbyterian Hospital in the City of New York. Vol. IV., January, 1900. Edited by Andrew J. McCosh, M.D., and W. Gilman Thompson, M.D. New York: Trow Directory Printing and Bookbinding Company.

This report contains the usual number of papers, some of which are illustrated. It is bound in conformity with previous issues.

Fliegenlarven als gelegentliche Parasiten des Menschen. Von Dr. Erich Peiper. Mit Abbildungen. Berlin: Verlag von Louis Marcus. 1900.

This is a small but entertaining and instructive dissertation on the fly, with forty-one illustrations and literary references.

Arzneiverordnungen in der Kinderpraxis für Studirende und Aerzte. Bearbeitet von Dr. med. H. Guttmann. Dritte gemäss dem Arzneibuche für das Deutsche Reich von 1901 vollständig umgearbeitete Auflage. Berlin: S. Karger. 1901.

This is a most admirable little book in that it gives in alphabetical order the more common and newer drugs used in pædiatric practice, with their doses, methods of applications, contraindications, dangers, etc. Many useful formulæ are scattered through the work, and its pages are interleaved for additional notes. One wonders but little that this volume has reached its third edition. Its portability enhances its value.

A Book of Detachable Diet Lists for Albuminuria, Anæmia and Debility, Constipation, Diabetes, Diarrhœa, Dyspepsia, Fevers, Gout or Uric-Acid Diathesis, Obesity, Tuberculosis, and a Sick-Room Dietary. Compiled by Jerome B. Thomas, Jr., A.B., M.D., Instructor in Materia Medica, Long Island College Hospital; Assistant Bacteriologist to Hoagland Laboratory. Second edition, revised. Philadelphia. W. B. Saunders. 1900.

The second edition of this very attractive collection of diet lists should meet with considerable success, since the author has chosen carefully yet liberally from a large variety of food stuffs and has left space for special additions to particular cases. A stub remains in the volume, thus affording a record of the date and the diet chosen for each patient. The sick-room dietary gives some very valuable recipes specially adapted to invalids and convalescents, and the appendix describes the method of rectal alimentation, together with the manner of preparing food for such cases.

Studies in the Psychology of Sex, the Evolution of Modesty, the Phenomena of Sexual Periodicity; Auto-Erotism. By Havelock Ellis. Philadelphia, New York, Chicago: The F. A. Davis Co. 1900.

The title indicates in a general way the ground covered by this interesting volume, but the preface must be read to get an idea of the author's aims and intentions. The book is offered as a preliminary contribution, to be followed by essays upon cognate subjects. There are three essays in this volume, in the first two of which there is much collated material of interest to the psychologist and anthropologist. The chapter on auto-erotism touches upon a subject which has not so far perhaps been discussed, as here, from the point of view of the psychologist and not the clinician. The views of the latter have, of course, their own importance, but to get a true conception of the workings of the human organism under certain conditions and to be able to come to satisfactory conclusions we must turn to the former and divest ourselves of most of the ideas engendered by the study of what most of us look upon as purely pathological manifestations. This author emphasizes the importance of clearing our minds of such conceptions if we are to study intelligently the phenomena of which he treats, and he promises further contributions from his own pen, which cannot fail to be of interest. The field is perhaps narrow, but it is important and in some of its aspects it touches the foundations of modern society, perhaps with a somewhat rude and insistent shock. There have been several recent publications upon similar subjects, but we think none which has handled them with so little offensive and unnecessary detail, for in this volume there is practically nothing objectionable.

Electro-therapeutics and x-Rays. By Dr. Charles Sinclaire Elliott, Author of "Lectures on Nervous and Mental Diseases," etc. Philadelphia: Boericke & Tafel. 1900.

We have in this work a handbook for the use of those who wish to employ electricity in its various forms both in surgical and neurological conditions. The conclusions drawn are almost entirely personal and consequently have not the force which appertains to the epitomized ideas of a number of observers, but the descriptions are usually clear and detailed. There is a section on the subject of *x*-rays which covers the subject in a fairly satisfactory manner.

Appendicitis and its Surgical Treatment, with a Report of One Hundred and Eighty-five Cases. By Herman Mynter, M.D., Professor of Clinical Surgery in the University of Buffalo. Third revised edition. Philadelphia and London: J. B. Lippincott Co. 1900.

This monograph on appendicitis is a revision of one printed about three years ago. It is somewhat enlarged, but does not differ in important detail. There is an interesting *résumé* of the views upon the subject in foreign countries which shows clearly that Americans have nothing to learn from Europe in this regard. The views expressed do not differ from those which are now recognized as best in this country, which is to say that they are sound.

Anleitung zur Diagnose und Therapie der Kehlkopf-Nasen- und Ohrenkrankheiten. Vorlesungen gehalten in Fortbildungscursen für practische Aerzte von Dr. Richard Kayser in Breslau. Mit 121 Abbildungen. Berlin: S. Karger. 1901.

This most practical book fulfils the object for which it was written, namely, to present in most condensed form the more common and typical conditions of the nose, ear, and throat as seen in every-day practice, leaving the more special therapeutic and operative procedures to the larger works. The author's experience as a teacher of practitioners has stood him in good stead, for the method of presentation is clear and concise, and the illustrations are of a most comprehensive nature. It is the first German work of its kind in that it embraces the three branches in one.

Kurzgefasstes Lehrbuch der Kinderheilkunde für Aerzte und Studirende. Von Dr. Carl Seitz. Berlin: S. Karger. 1901.

In the preface the author expresses as his object the presentation of a comprehensive and at the same time a short and concise work on diseases of children. As one peruses the pages he soon finds that the volume is larger than he looked forward to, very comprehensive but by no means short. The divisions and subdivisions follow the regulation text-book order, a general and special part, examination and feeding of healthy and sick infants and children, diseases of the new-born, affections of the nose, eye, ear, throat, and skin, etc. The print is subdivided into large and small, the former being devoted to the more general conditions and therapeutic remedies, the latter to special and rare matters. All in all, the work can be recommended as a good text-book on the subject and as a reference for some of the anomalies and rarities of infancy and childhood.

Edinburgh Hospital Reports. Published under the supervision of the editorial committee of Royal Infirmary, Royal Hospital for Sick Children, and Royal Maternity and Simpson Memorial Hospital. Edited by G. A. Gibson, M.D., D.Sc., C. W. Cathcart, M.A., M.B., John Thomson, M.D., D. Berry Hart, M.D. Illustrated with colored plates and engravings. Volumes I., II., III., IV., V., VI. Edinburgh and London: Young J. Pentland. 1900.

Begun in 1893, this annual report has provided an interesting means of reviewing the yearly work done in the various departments of the hospital. The first volume contains brief sketches of the rise and progress of the institution concerned. The subjects are so arranged that they fall

into natural groups and contributions appear from past as well as from present staff members. These volumes, containing each from over four hundred to over seven hundred pages, and being handsomely printed and bound, are not "reports," in the usual acceptation of the term, but contain carefully prepared essays and dissertations upon new, rare, and important subjects, besides the statistical matter and tables usually presented. A very valuable collection of facts has been made possible by the generosity and unselfish energy and enterprise of the gentlemen connected with hospitals of Edinburgh and Leith, and their contributions will have an ever-increasing value. In the last report is included a portion of the manuscript left by the late Mr. John Duncan, dealing with "Electrolysis in Aneurism" and "Angioma," which adds not a little to the interest attached to the work. The collection as a whole makes a pleasing bond of union between old and new members of the Edinburgh school, and reflects great credit upon the latter, the editing committee, and the various contributors.

Transactions of the Vermont State Medical Society, 1899. Published by the Society. D. C. Hawley, M.D., secretary. Annual meeting in 1900, at Rutland, October 11th and 12th. Burlington: Free Press Association. 1900.

Two hundred and twenty-seven pages, including list of members, various reports of officers, and papers read make a very creditable bound volume. Prof. John B. Wheeler contributes an article on surgery in its relation to the female pelvic organs, and Richardson, of Boston, on perforating gastric ulcer.

Air, Water, and Food from a Sanitary Standpoint. By Ellen H. Richards and Alpheus G. Woodman, Instructors in Sanitary Chemistry, Massachusetts Institute of Technology. First edition. New York: John Wiley & Sons. London: Chapman & Hall, Limited. 1900.

This 8vo of two hundred and twenty-six pages deals with the three essentials of human existence from various standpoints and points out many a true lesson in the avoidance of disease by renouncing doubtful articles of diet, including those contaminated by adulteration. The ethical and hygienic sides of the question of food adulteration are both discussed. A very important chapter is that discussing analytical methods. Much thought and research have evidently been expended in the preparation of the work.

Transactions of the American Otological Society. Thirty-third Annual Meeting, held at Washington, D. C., May, 1900. Vol. VII., Part III., of the Society's Transactions. Published by the Society. New Bedford, Mass.: Mercury Publishing Company, Printers. 1900.

This well-printed pamphlet contains seven papers with discussions thereon. A valuable feature is an alphabetical index of otological bibliography for the year, from June 1, 1899, to June 1, 1900, compiled by Dr. Henry A. Alderton, of Brooklyn. The general characteristics of the work are fully up to the high standard of this well-known society.

Short Papers on Nursing Subjects. By L. L. Dock. New York: M. Louise Longeway, publisher. 1900.

Nursing organizations in Germany and England are compared, and the Nurses' Settlement in New York is described. Other matter is of interest to nurses and those who watch their work.

Clinical Studies in Epilepsy: from the Craig Colony for Epileptics at Sonyea, N. Y. By L. Pierce Clark. I. Exhaustion-Paralysis in Epilepsy. II. Paramyoclonus Multiplex Associated with Epilepsy. III. Hypertrophic Infantile Cerebral Palsy and Phocomelus Associated with Epilepsy. Utica, N. Y.: State Hospitals Press. 1900.
